 Wilson, David - Pennsylvania State University
 Witt, Robert - University of Texas, Austin
 Zaltman, Gerald - University of Pittsburgh

PREFACE

In October, 1980, the Association for Consumer Research (ACR) held its Eleventh Annual Conference. This conference opened a new decade for consumer research marking a major step in maturity for ACR, and presenting new challenges and opportunities for the advancement of consumer research.

In recognition of these challenges and opportunities, the program committee sought to have sessions that highlighted current and future issues in consumer research. Moreover, the committee sought to utilize the conference location, Washington D.C., and include public policy as a major programmatic focus.

Volume VIII of the Advances in Consumer Research series contains most of the presentations made at the 1980 conference. All of the competitive papers and most of the discussants' commentaries are included here. We were also able, sometimes with a little persuasion, to publish most of the presentations made at the special topics sessions and workshops. The Presidential Address by Dr. William L. Wilkie is included as are the special remarks made by the first two fellows of the Association for Consumer Research, Dr. James F. Engel and Dr. John A. Howard.

A number of people contributed to the success of the conference and to this volume. The key contributions were made by the authors and the organizers of the special sessions and workshops. The paper reviewers listed on p. iv made substantive contributions by judging the 113 paper submissions and providing authors of accepted papers with suggestions for improving their papers. The Program Committee evaluated all special session proposals, offered me encouragement when needed, and took a lead in developing sessions fitting the theme of the conference. Special thanks goes to Paul N. Bloom and to Gary T. Ford for helping with arrangements and registration. We also received excellent support from the staff of the Key Bridge Marriott Hotel.

At Virginia Tech, many people made outstanding contributions. John McGinnis, William Middleton and Micky Nguyen provided early assistance in organizing the tasks to be done, stuffing envelopes, and recording reviewers' judgments. R. Krishnan provided invaluable assistance in computerizing our operations and providing the day-to-day assistance throughout the registration period. Ramon Avila continued the post-registration computer work and Nelson Craige compiled, paged, and indexed the Proceedings. Wanda Belcher and Janice Blevins provided secretarial assistance, and my secretary Becky Glick handled the correspondence and telephone calls for me. Molly Hobson, University of Maryland, assisted Gary Ford and provided registration help during the conference. Artistic work was done by John Board.

Special thanks goes to Allyn Kosenko who proofed, edited and re-typed the manuscripts. She simply did a fantastic job! The support provided by Virginia Tech and the Marketing faculty is also gratefully acknowledged.

1980 PROGRAM: ANNUAL CONFERENCE OF THE ASSOCIATION FOR CONSUMER RESEARCH

Thursday, October 16, 1980

Executive Committee Meeting: 10:00 a.m. - 3:00 p.m., *Monroe Room*
Registration opens at 2:00 p.m. and closes at 8:00 p.m., Lobby Level

Special Event: 3:30 p.m. - 5:15 p.m. (attendance limited)
PUBLIC POLICY UPDATE: PERSPECTIVES ON THE FEDERAL TRADE COMMISSION

Commissioners' Conference Room, Federal Trade Commission

The purpose of this special session is to provide ACR members with an update on current and prospective issues under consideration at the FTC.

CHAIR: Kenneth L. Bernhardt, Georgia State University

Participants:

1. Bob Reich, Director of the Office of Policy Planning, FTC. He will discuss consumer issues for the 1980's outlining his views on issues that ACR members should be tracking. He will comment on the increased orientation toward providing consumers with useful information, use of performance standards, sunset legislation, and increased use of cost/benefit analysis.
2. Ron Stiff, Regulatory Analysis/Impact Evaluation Office, Bureau of Consumer Protection. He will discuss current and future consumer research activities at the agency.
3. Michael Pertschuk, Chairman, Federal Trade Commission. He will provide his perspective on current and future policy issues being studied by the Commission. He will also comment on the use of consumer research in FTC policy.

EARLY BIRD RECEPTION: 6:00 p.m. - 8:00 p.m. (cash bar), Potomac Ballroom

FRIDAY, OCTOBER 17, 1980

Registration opens at 8:00 a.m. and closes at 6:00 p.m.

MORNING SESSIONS - 1

8:30 a.m. - 10:00 a.m.

Special Topic Session (3 hrs): EMERGING ISSUES IN LOW INVOLVEMENT THEORY

Francis Scott Key Room, Salon A

CHAIR: Richard J. Lutz, Univ. of California, Los Angeles
John T. Cacioppo, University of Iowa

This session seeks to clarify the conceptual properties of the low involvement construct and to provide direction for future research. The papers address the implications of involvement for understanding consumer behavior.

What is Low Involvement Low In?

Clark Leavitt, Ohio State University
Anthony G. Greenwald, Ohio State University
Carl Obermiller, Ohio State University

Issue Involvement as a Moderator of the Effects on Attitude of Advertising Content and Context

Richard E. Petty, University of Missouri
John T. Cacioppo, University of Iowa

The Dimensions of Advertising Involvement

Andrew A. Mitchell, Carnegie-Mellon University

Reconceptualizing Consumer Involvement

Richard J. Lutz, Univ. of California, Los Angeles

Discussant: Harold H. Kassarjian, Univ. of California, Los Angeles

Special Topic Session: THE NEGATIVE SIDE OF CONSUMER INFORMATION

Francis Scott Key Room, Salon B

CHAIR: Marc G. Weinberger, Univ. of Massachusetts, Amherst
Chris T. Allen, Univ. of Massachusetts, Amherst
William R. Dillon, Univ. of Massachusetts, Amherst

The full impact of negative product information on consumers is unknown, but preliminary research suggests that negative information can have a powerful influence on buyers. This session summarizes prior research on negative information, discusses current research, and offers some theoretical explanations for the empirical results.

Negative Information: Perspectives and Research Directions

Marc G. Weinberger, Univ. of Massachusetts, Amherst
Chris T. Allen, Univ. of Massachusetts, Amherst
William R. Dillon, Univ. of Massachusetts, Amherst

Factors Influencing Consumer Responses to Product Recalls: A Regression Analysis Approach

John C. Mowen, Oklahoma State University
David W. Jolly, Oklahoma State University
Gary S. Nickell, Oklahoma State University

Theoretical Perspectives on the Impact of Negative Information

Carol A. Scott, Univ. of California, Los Angeles
Alice M. Tybout, Northwestern University

Negative Information: A Commentary

Stephen A. Greyser, Harvard University/Marketing Science Institute

BREAK: Coffee and Soft Drinks

Lobby Level and Lower Level

10:00 a.m. - 10:30 a.m.

Special Topic Session: PUBLIC POLICY AND CONSUMER
RESEARCH IN THE 1980's

Georgetown Room, Salons A,B

CHAIR: Paul N. Bloom, Marketing Science Institute

This session identifies probable public policy issues of the 1980's that might be resolvable with appropriate consumer research. The purpose of the session is to provide an "early warning" on issues so that relevant consumer research could be completed in time to influence formulated policies

The Future of Consumer Protection Regulation
Michael B. Mazis, American University

Consumer Policy Issues: Global Trends for the 1980's
Graham T. T. Molitor, Public Policy Forecasting,
Inc.

Judging Marketing in the 1980's
Alan R. Andreasen, University of Illinois, Urbana

*The Swedish Experience: Its Transferability and Related
Research Implications*
Hans B. Thorelli, Indiana University

Paper Session: CONSUMER RESEARCH AND QUALITY OF LIFE

Georgetown Room, Salon C

CHAIR: Pravat K. Choudhury, Howard University

*Leisure and the QOL Construct: A Review and Some Modest
Proposals*

Lynette S. Unger, Miami University
Jerome B. Kernan, University of Cincinnati

The Consumer and the Health Care Process
Lynn Langmeyer, Wright State University
George Miaoulis, Wright State University

*Attitudes Toward Public Policy Alternatives to Reduce Air
Pollution*

David A. Aaker, Univ. of California, Berkeley
Richard P. Bagozzi, Massachusetts Institute of
Technology

Discussant: William G. Zikmund, Oklahoma State Univ.

Paper Session: COGNITIVE PROCESSES

Potomac Ballroom, Salon D

CHAIR: Albert R. Wildt, University of Georgia

Toward Conceptualizing and Measuring Cognitive Structures
Rajesh Kanwar, The Pennsylvania State University
Jerry C. Olson, The Pennsylvania State University
Laura S. Sims, The Pennsylvania State University

Cognitive Maps and Shopping Convenience
Sanford Grossbart, University of Nebraska
Balusu Rammohan, University of Nebraska

*A Method for Determining the Sequencing of Cognitive Pro-
cesses in Judgment: Order Effects on Reaction Times*
John G. Lynch, Jr., University of Florida

Discussant: Michael J. Ryan, Columbia University

BREAK: Coffee and Soft Drinks Lobby Level and Lower Level

10:00 a.m. - 10:30 a.m.

Special Topic Session: EMERGING ISSUES IN LOW INVOLVEMENT THEORY

*Francis Scott Key Room, Salon A*CHAIR: Richard J. Lutz, Univ. of California, Los Angeles
John T. Cacioppo, University of Iowa

[Continued from 8:30]

Special Topic Session: USING THE BUREAU OF LABOR STATISTICS CONSUMER EXPENDITURE SURVEY IN CONSUMER RESEARCH

*Potomac Ballroom, Salon D*CHAIR: Seymour Sudman, Univ. of Illinois, Urbana
Gregory D. Upah, Virginia Tech

The Consumer Expenditure Survey consists of: (1) a quarterly interview panel, and (2) a diary completed by each respondent for two weeks. The data are used in the formulation of public policy. The purposes of this session are to describe the CES and its methodology and to illustrate how this longitudinal data may be used in consumer research.

Overview of the Consumer Expenditure Survey
Gail Hoff, Bureau of the Census*Uses of the Consumer Expenditure Survey Data*
Eva Jacobs, Bureau of Labor Statistics*An Evaluation of the 1972-73 Consumer Expenditure Survey Data*

Robert Pearl, Univ. of Illinois, Urbana

*The Consumer Expenditure Survey: Prospects for Consumer Research*Gregory D. Upah, Virginia Tech
Seymour Sudman, Univ. of Illinois, Urbana

Paper Session: CONSUMER RESPONSE TO ADVERTISING

Georgetown Room, Salon C

CHAIR: Mary Jane Schlinger, Univ. of Illinois, Chicago Circle

*Linear Effects of Cognitive Response to Advertising*Larry Percy, Creamer, Inc.
Martin R. Lautman, Associates for Research in Behavior, Inc.*On Explaining and Predicting the Effectiveness of Celebrity Endorsers*John C. Mowen, Oklahoma State University
Stephen W. Brown, Arizona State University*Guilt Arousing Marketing Communications: An Unexplored Variable*

Morry Ghingold, Pennsylvania State University

Discussant: Robert L. King, Virginia Tech

Special Topic Session: UNIVERSITY PANELS FOR CONSUMER RESEARCH

*Georgetown Room, Salons A,B*CHAIR: Kenneth L. Bernhardt, Georgia State Univ.
William R. Darden, Univ. of Arkansas

This session introduces consumer researchers to academic-sponsored consumer research panels. The purposes of the session are to discuss the design of these panels and to illustrate their value for consumer research. The discussion will also focus on the operation and maintenance of these consumer research panels.

*Research Panels in Consumer Behavior*Robert Ferber, Univ. of Illinois, Urbana
Linda B. Lannom, Univ. of Illinois, Urbana*Perspectives on Academically-Oriented Panel Research*Arch Woodside, University of South Carolina
Jesse Teal, University of South Carolina*Surveys of Consumer Attitudes: Survey Research Center, University of Michigan*

Richard Curtin, Consumer Sentiment Panel

Discussants: Richard B. Ross, Market Facts, Inc.
C. Whan Park, University of Pittsburgh

Paper Session: DEVELOPING NEW RESEARCH TRADITIONS IN CONSUMER RESEARCH

Francis Scott Key Room, Salon B

CHAIR: Debra L. Scammon, University of Utah

*The Impact of Program Evaluation Needs on Research Methodology*R. Bruce Hutton, University of Denver
Dennis L. McNeill, University of Denver*Risk-Benefit Analysis and the Determination of Acceptable Risk*Rachel Dardis, University of Maryland
Julie Stremel, University of Maryland*Scientific Progress and Research Traditions in Consumer Research*Liisa Uusitalo, International Institute for Environment and Society, West Germany
Jyrki Uusitalo, University of Helsinki

Discussant: Peter D. Bennett, Pennsylvania State Univ.

LUNCHEON Potomac Ballroom
Guest Speakers - James F. Engel - John A. Howard

12:00 p.m. - 1:30 p.m.

Special Topic Session (3 hrs.): THE ROLE OF CONSUMER RESEARCH IN THE FORMATION OF PUBLIC POLICY: AN EXAMPLE OF AN INTEGRATED RESEARCH AND DEVELOPMENT PLAN

Francis Scott Key Room, Salon A

CHAIR: James T. Heimbach, Food & Drug Administration

Since Spring 1978, the Food and Drug Administration (FDA) has been executing a large, integrated research plan for the purpose of revising the current information content of the food label. This research plan is a unique example of the application of consumer research to an issue of public policy. This session presents the research plan and highlights the current research results.

Defining the Problem: The Scope of Consumer Concern with Food Labeling

James T. Heimbach, Food & Drug Administration

Food Label Information: What Consumers Say They Want and What They Need

Edwin C. Hackleman, Food & Drug Administration

Food Label Information: What Consumers Say They Use and What They Actually Use

Michael H. Baumgardner, Food & Drug Administration

Commercial Market Tracking Systems: Applications to Policy Formation Regarding Labeling

Michael L. Stewart, Food & Drug Administration

Labels That Communicate: Design and Evaluation

Raymond C. Stokes, Food & Drug Administration

Implementation of a Revised Food Labeling Policy: Evaluation and Tracking

Raymond E. Schucker, Food & Drug Administration

Workshop (3 hrs.): ASSESSING CORRECTIVE ADVERTISING EFFECTS

Georgetown Room, Salons A,B

CHAIR: William L. Wilkie, Univ. of Florida

This session presents the empirical research results from several corrective advertising campaigns. Previously unreported data dealing with the impact of STP and Listerine advertising will be presented. Jack Jacoby will present his very controversial research study examining the efficacy of the FTC's corrective advertising strategy.

Viewer Miscomprehension of Televised Communications

Jacob Jacoby, Purdue University
Wayne D. Hoyer, Purdue University
David A. Sheluga, Purdue University

Impact of Publicity on Corrective Advertising Effects

Kenneth Bernhardt, Georgia State University
Thomas Kinnear, University of Michigan

Correcting Corrective Advertising

Jacob Jacoby, Purdue University
Margaret C. Nelson, Purdue University
Wayne D. Hoyer, Purdue University

Recall of Corrective Commercials

Dennis McNeill, University of Denver

Attitude and Belief Changes from Corrective Ads

Gary Armstrong, University of North Carolina
Fritz Russ, University of North Carolina

A Longitudinal Study of Corrective Advertising

Michael Mazis, American University

Discussants: Peter Rheinstein, Food & Drug Administration
Richard D. Mizerski, Federal Trade Commission

Special Topic Session: PATRONAGE THEORY

Potomac Ballroom, Salon D

CHAIR: William R. Darden, University of Arkansas

This session and the following session on patronage research focuses on patronage choice behavior. In recent years, store choice behavior research has been limited both in terms of theoretical development and the research methods used, despite the large amounts spent on location research by retail firms. The patronage theory session develops the linkage between the traditional gravitational models and the behavioral models of patronage choice behavior. The patronage research session that follows discusses the newer research methods that are being used to gather evidence on store choice behavior.

Integration of Economic Geography and Social Psychological Models of Patronage Behavior

Robert F. Lusch, University of Oklahoma

Women's Self-Ascribed Occupational Status and Retail Patronage

Elizabeth C. Hirschman, New York University

Consumer Socialisation Factors in a Patronage Model of Consumer Behavior

William R. Darden, University of Arkansas

Donna K. Darden, University of Arkansas

Roy Howell, University of Illinois

Shirley Jo Miller, University of Arkansas

Discussant: Robert Peterson, Univ. of Texas, Austin

Paper Session: CONSUMER PERCEPTIONS

Francis Scott Key Room, Salon B

CHAIR: E. Laird Landon, University of Houston

A Multivariate Analysis of the Perception of Value from Retail Price Advertisements

Albert J. Della Bitta, University of Rhode Island

Kent B. Monroe, Virginia Tech

The Effect of Generic Products on Consumer Perceptions and Brand Choice

John J. Wheatley, University of Washington

Determinants of Consumption Cue Utilization in Impression Formation: An Associational Derivation and Experimental Verification

Russell W. Belk, University of Utah

Discussant: Eric N. Berkowitz, University of Minnesota

Paper Session: PERCEPTION OF TIME AND CONSUMER BEHAVIOR

Georgetown Room, Salon C

CHAIR: J. Paul Peter, Ohio State University

Temporal Links Between Preference and Perception

James McCullough, The University of Arizona

Douglas MacLachlan, University of Washington

Reza Moïnpour, University of Washington

Temporal Incongruency in Consumer Behavior

Philip E. Hendrix, University of Michigan

Claude R. Martin, Jr., University of Michigan

The Imagination of the Future: A Hidden Concept in the Study of Consumer Decision Making

Rebecca H. Holman, Young and Rubicam, Inc.

Discussant: Wesley T. Johnston, Ohio State Univ.

Special Topic Session: THE ROLE OF CONSUMER RESEARCH IN THE FORMATION OF PUBLIC POLICY: AN EXAMPLE OF AN INTEGRATED RESEARCH AND DEVELOPMENT PLAN

Francis Scott Key Room, Salon A

CHAIR: James T. Heimbach, Food & Drug Administration

[Continued from 1:30]

Workshop: ASSESSING CORRECTIVE ADVERTISING EFFECTS

Georgetown Room, Salons A,B

CHAIR: William Wilkie, University of Florida

[Continued from 1:30]

Paper Session: ATTITUDE RESEARCH AND BEHAVIORAL INTENTIONS

Francis Scott Key Room, Salon B

CHAIR: David T. Wilson, Pennsylvania State Univ.

Attitude Structure and Search: An Integrative Model of Importance Directed Information Processing

Morris B. Holbrook, Columbia University
David A. Velez, Columbia University
Gerard R. Tabouret, Columbia University

Examining the Diagnostic Validity of the Fishbein Behavioral Intention Model

Paul W. Miniard, Ohio State University

A Comparison of Two Behavioral Intention Models

David Brinberg, University of Maryland

Discussant: Paul R. Warshaw, McGill University
Jeffrey E. Danes, Virginia Polytechnic and State University

Special Topic Session: PATRONAGE RESEARCH APPLICATIONS AND METHODS

Potomac Ballroom, Salon D

CHAIR: William R. Darden, University of Arkansas

An Exploratory Investigation of Mediating Factors in Retail Store Image Responses

Robert Peterson, Univ. of Texas, Austin

A Comparison Between Discriminant Analysis and Multinomial Logit in the Prediction of Store Choice

Douglas Tigert, University of Toronto
Victor Roth, University of Toronto

Research into Shopping Mall Choice Behavior

Roy Howell, Univ. of Illinois, Urbana
Jerry Rogers, Southwest Missouri State University

Discussant: Thomas Stanley, Georgia State Univ.

Paper Session: SOCIAL CLASS AND SOCIAL INFLUENCE

Georgetown Room, Salon C

CHAIR: Ivan Ross, University of Minnesota

Perceived Differences in Product and Brand User Stereotypes Across Upper, Middle and Lower Social Classes

J. Michael Munson, University of Santa Clara
W. Austin Spivey, University of Santa Clara

Proposed Extensions of the Basic Model of Social Class Employed in Consumer Research

Terence A. Shimp, University of South Carolina
J. Thomas Yokum, University of South Carolina

An Analysis of Alcohol Advertisements Using French and Raven's Theory of Social Influence

Scott B. Mackenzie, Univ. of California, Los Angeles
Judy L. Zaichkowsky, Univ. of California, Los Angeles

Discussant: Barton Weitz, Univ. of California, Los Angeles

BUSINESS MEETING	Georgetown Room, Salons A,B	5:00 p.m. - 5:30 p.m.
	EVERYONE IS WELCOME TO ATTEND	
RECEPTION (Cash bar)	Potomac Ball Room	6:00 p.m. - 8:00 p.m.
DINNER ON YOUR OWN		

SATURDAY, OCTOBER 18, 1980

Registration opens 8:00 a.m., and closes at 3:00 p.m.

Jogging Along the Potomac, Shirts Sponsored by Prentice-Hall, Inc.
Meet Gary Ford in the Lobby 6:15 a.m.

MORNING SESSIONS - 1

8:30 a.m. - 10:00 a.m.

Special Topic Session: CONSUMER INFORMATION: IMPROVING
THE INTERACTION BETWEEN SUPPLY
AND DEMAND

Georgetown Room, Salons A,B

CHAIR: Hans B. Thorelli, Indiana University

Past research on the need for and design of consumer information has primarily focused on the consumer as a buyer, but has largely neglected the fact that early research and public policy focused on the idea that consumer information was necessary for the smooth functioning of the market system. The purpose of this session is to focus on research that examines the impact of consumer information on the interdependencies among sellers behaviors, market structure, and market performance.

Consumer Information and Workability of Competition - A Theoretical Framework

Guenter Schoeppe, University of Frankfurt
Christine Czerwonka, University of Frankfurt

The Influence of Product Test Reports on Suppliers' Behavior

Hans Raffee, University of Mannheim
Guenter Silberer, University of Mannheim
Wolfgang Fritz, University of Mannheim
Harald Hilger, University of Mannheim
Bernd Kierdorf, University of Mannheim

Sources for Product Ideas: A Proactive View on the Consumer

Gerd Fleischmann, University of Frankfurt

Perceived Risk as a Hint for Better Consumer Information and Better Products: Some New Applications of an Old Concept

Klaus G. Grunert, University of Hohenheim
Ingrid Gottschalk, University of Hohenheim
Konrad Dedler, University of Hohenheim

Discussant: Edward J. Heiden, Kirschner Associates

Special Topic Session (3 hrs.): WOMEN'S ROLES - AT WORK,
AT HOME, AND IN THE
MARKET PLACE

Francis Scott Key Room, Salon A

CHAIR: Mary Lou Roberts, Boston University

This session brings together leading scholars from several areas of study about women. The speakers present areas of basic research in the behavioral sciences that form the foundation for research into various aspects of women's consumer behavior. The purpose of the session is to stimulate more applied research in women's consumer behavior.

Behavioral Science Research on Women - Status, Problems and Prospects

Virginia E. O'Leary, American Psychological Association

An Evaluation of Sex Role Theories: The Clash Between Idealism and Reality

Susan Hesselbart, Florida State University

Housewives, Breadwinners, Mothers and Family Heads: The Changing Family Roles of Women

Janet Kohen, San Diego State University and the Institute for Social Research, University of Michigan

Psychological and Sociological Perspectives on Women's Paid and Unpaid Work Choices

Ruth B. Ekstrom, Educational Testing Service

Women in Paid Work: Some Consequences and Questions for Family Income and Expenditures

Hilda Kahne, Wheaton College

Women's Changing Roles: A Consumer Behavior Perspective

Mary Lou Roberts, Boston University

REAK: Coffee and Soft Drinks Lobby Level and Lower Level

10:00 a.m. - 10:30 a.m.

Panel Discussion: THE TRAINING AND CARING OF A CONSUMER RESEARCHER

Francis Scott Key Room, Salon B

CHAIR: Alan Sawyer, Ohio State University

The members of this panel will discuss ways to train a skilled consumer researcher. Panel participants and the audience will discuss issues such as theory vs application, how-to-do research courses vs practicum courses, business or government research career objectives vs an academic research career. The panel will also discuss priorities among different types of courses or seminars.

Panelists: Joel Cohen, University of Florida
Fred Reynolds, University of Georgia
Gerald Zaltman, University of Pittsburgh
Lawrence D. Gibson, General Mills, Inc.

Paper Session: NEW INSIGHTS FOR CONSUMER INFORMATION PROCESSING

Potomac Ballroom, Salon D

CHAIR: Murphy Sewall, University of Connecticut

A Consumer Based Approach for Establishing Priorities in Consumer Information Programs: Implications for Public Policy

Rohit Deshpande, University of Texas, Austin
S. Krishnan, Pennsylvania State University

Inferential Belief Formation Through the Use of Non-Information: An Example

David W. Finn, Texas Christian University

An Examination of Information Processing Traits: General Social Confidence and Information Processing Confidence

James M. Munch, Pennsylvania State Univ.
John L. Swasy, Pennsylvania State Univ.

Discussant: Jagdish Sheth, University of Illinois, Urbana

Paper Session: DIFFERENT CULTURES AND SEGMENTATION ANALYSIS

Georgetown Room, Salon C

CHAIR: P. J. O'Connor, University of Kentucky

The Influence of Geographic Subcultures in the United States

Kenneth A. Coney, Arizona State University
Del I. Hawkins, University of Oregon
Donald Roupe, University of Oregon

Consumerism in Developing Countries: The Brazilian Experience

J. Stanton, Temple University
R. Chandran, Temple University
J. Lowenhar, Temple University

Testing the Stability of Market Segmentation Analysis

D. A. Schellinck, Dalhousie University
Ian Fenwick, Northeastern University

Discussant: Roger M. Heeler, York University

Special Topic Session: WOMEN'S ROLES - AT WORK, AT HOME,
AND IN THE MARKET PLACE*Francis Scott Key Room, Salon A*

CHAIR: Mary Lou Roberts, Boston University

[Continued from 8:30]

Special Topic Session: BROADENING THE DIMENSIONS OF THE
AGE VARIABLE IN CONSUMER BEHAVIOR*Potomac Ballroom, Salon D*CHAIR: Leon G. Schiffman, City University of New York
(Baruch College)

The three papers in this session discuss the measurement and/or analysis of age in ways not usually considered in consumer research. These papers offer some new thinking on age as a variable including cohort analysis, age stereotypes, and self-perceived age. Implications for future consumer research are also discussed.

*Separating Age Cohort and Period Effects in Consumer Behavior*Fred D. Reynolds, University of Georgia
Joseph O. Rentz, University of Virginia*Cognitive Age: A Nonchronological Age Variable*Leon G. Schiffman, City University of New York
(Baruch College)
Benny Barak, Rutgers University*Issues in the Measurement and Use of Chronological and Non-chronological Age*Gerald Zaltman, University of Pittsburgh
Mark I. Alpert, University of Texas, Austin
Michael Heffring, University of Calgary

Discussant: Nora Ganim Barnes, Boston College

Special Topic Session: THE CONSUMER IN THE PUBLIC SECTOR:
APPROACHES TO ACCEPTABLE RISK*Georgetown Room, Salons A,B*

CHAIR: M. Venkatesan, University of Oregon

The purpose of this session is to discuss research approaches to determine the "safe" levels relative to products and public goods where there may be a number of hazards involved. Such issues range from the containment problems around nuclear plants to carcinogenicity of saccharine. The issues discussed are at the frontier of consumer research.

Approaches to Acceptable Risk: A Brief Summary
Paul Slovic, Decision Research*Approaches to Acceptable Risk: Their Relevance to Research in Consumer Behavior in the Public Sector*
M. Venkatesan, University of Oregon*Towards Determinants of Acceptable Risk: The Case of Product Risk*Arno Rethans, Pennsylvania State University
Gerald S. Albaum, University of Oregon

Discussant: Jacob Jacoby, Purdue University

Workshop: SURVEY RESPONSE RATES: DO WE KNOW WHERE THESE
PROBLEMS CAN LEAD?*Francis Scott Key Room, Salon B*

CHAIR: Joy Williams-Jones, Marketing Science Institute

Survey research is widely used for market analysis and is becoming accepted as evidence in legal proceedings. However, the application of many statistical tests to survey data is suspect unless a relatively high response rate is obtained. Moreover, some governmental agencies now require high response rates for a research-based testimony to be credible. The difficulty is there seems to be no mutually agreed upon definition for "response rate." The papers in this session highlight the nature of this research problem in terms of research replication, manuscript evaluation, and expert testimony. Research into the issue of an increased tendency of people not to respond will also be reported.

Non-Response in Consumer Surveys

Fred Wiseman, Northeastern University

Reporting of Response Rates in Professional Literature and the Ability to Replicate

Robert A. Mittelstaedt, Univ. of Nebraska, Lincoln

The Role of Response Rates in Evaluating Manuscripts for Publications

Robert Ferber, University of Illinois

Controversy in Washington: An FTC Case

Irving Roshwalb, Audits & Surveys Inc.

Lack of Agreement on the Standardization of Response rate Terminology in the Survey Research Industry

Joy Williams-Jones, Marketing Science Institute

Discussant: Keith Hunt, Brigham Young University

Paper Session: MULTI ATTRIBUTE SCALING MODELS

Georgetown Room, Salon C

CHAIR: Naresh Malhotra, Georgia Institute of Technology

*Two Models for Representing Unrestricted Choice Data*Paul E. Green, University of Pennsylvania
Wayne S. DeSarbo, Bell Laboratories*Limits to Accuracy in Conjoint Analysis*Franklin Acito, Indiana University
Richard W. Olshavsky, Indiana University*On Alternative Methodological Procedures for Conjoint Measurement*Thomas W. Leigh, Indiana University
David B. MacKay, Indiana University
John O. Summers, Indiana UniversityDiscussants: Jeffrey E. Danes, Virginia Tech
Philippe Cattin, Univ. of Connecticut

LUNCHEON

Awards Presentation,

Potomac Ballroom

Presidential Address: William L. Wilkie, University of Florida

12:00 p.m. - 1:30 p.m.

Special Topic Session: APPROACHES FOR DEVELOPING CAUSAL MODELS IN CONSUMER RESEARCH

Georgetown Room, Salons A,B

CHAIR: Kent B. Monroe, Virginia Tech

It has become increasingly apparent that an appropriate method to test empirically the complex models of consumer behavior is through the use of structural equation models. Indeed, the issue of model identification made explicit by the structural equation approach raises the question of whether most consumer research efforts are valid. Each speaker, in a tutorial approach, shows the steps from theory to model building, to estimation and hypothesis testing, to issues of validity. Step-by-step empirical examples are used.

Causal Modeling: A General Method for Developing and Testing Theories in Consumer Research

Richard P. Bagozzi, Massachusetts Institute of Technology

A Comparison of Causal Path and Econometric Modeling Approaches

Leonard Parsons, Georgia Institute of Technology

Investigating Causal Systems with Qualitative Variables: Goodman's Wonderful World of Logits

William R. Dillon, Univ. of Massachusetts, Amherst

Special Topic Session (3 hrs.): THE CONSUMER IN THE PUBLIC SECTOR

Francis Scott Key Room, Salon A

CHAIR: Kristian S. Palda, Queens University

When individuals vote for a political candidate or vote for a bond issue for public goods, behaviorally they are acting similarly as the consumer who "votes" for a brand of cereal at the supermarket. However, researchers recently have raised the question of whether "consumers" indeed have sufficient information about these public goods they are "buying." Viewing the citizen-taxpayer as a consumer raises many economic and behavioral research questions needing further attention. The papers in this session present current research on the consumer as a taxpayer who acquires public goods and the consumer as a voter.

Individual Preferences and Public Policy

Robert T. Deacon, Univ. of California, Santa Barbara

Substitution Between Public and Private Goods: An Overview of The Market Meeting Consumer Preferences

Charles L. Vehorn, General Accounting Office

*Consumer Information About Public Goods and The Workability of the Welfare State*Martin Pfaff, International Institute for Empirical Social Economics
Ernst Kistler, International Institute for Empirical Social Economics*Voting Participation in a Public Consumption Perspective*Randall G. Chapman, Queens University
Kristian S. Palda, Queens University*Measuring Subjective Valuation and Demand for Government Services*

Eli M. Noam, Columbia University

Fiscal Illusion and Consumer Sovereignty: An Exploratory Study

W. W. Pommerehne, Universitaet Zurich

Discussant: Robert Ferber, Univ. of Illinois, Urbana

Special Topic Session: HIGH TECHNOLOGY RESEARCH IN CONSUMER BEHAVIOR

Francis Scott Key Room, Salon B

CHAIR: Martin R. Lautman, Associates for Research in Behavior, Inc.
Richard C. Reizenstein, Univ. of Tennessee

The purpose of this session is to present applications of the "newest" research techniques in applied settings. Each panelist presents several examples of how state-of-the-art research has been used in a study within their company. Special emphasis is placed on "new methodological wrinkles" necessitated by doing large scale consumer research.

Forecasting Military Enlistment Decision Making
Al Martin, Office of the Secretary of Defense, Pentagon

Quantitative Modeling and Advertising Accountability
Lew Pringle, Director of Research, BBDO

From the Consumer Decision Process to Marketing: the Case for Micro Behavioral Simulation
Harry Sunenshine, Director of Research, Heublein
Richard Westwood, Beaumont Organization

Paper Session: THE EFFECT OF PRODUCT FAMILIARITY ON CONSUMER BEHAVIOR

Potomac Ballroom, Salon D

CHAIR: Melanie R. Wallendorf, Univ. of Michigan

The Moderating Effects of Cognitive Complexity and Prior Product Familiarity on the Predictive Ability of Selected Multi-Attribute Choice Models for Three Consumer Products

Chin Tiong Tan, University of Singapore, Singapore
Ira J. Dolich, Univ. of Nebraska, Lincoln

Toward a Cognitive Structure Conceptualization of Product Familiarity

Lawrence J. Marks, Pennsylvania State Univ.
Jerry C. Olson, Pennsylvania State Univ.

Discussant: Michael Rothschild, Univ. of Wisconsin, Madison

Special Topic Session: THE CONSUMER IN THE PUBLIC SECTOR

Francis Scott Key Room, Salon A

CHAIR: Kristian S. Palda, Queens University

[Continued from 1:30]

Special Topic Session: METHODOLOGICAL ISSUES IN USING
PANEL DATA FOR MODEL BUILDING*Francis Scott Key Room, Salon B*

CHAIR: Donald R. Lehmann, Columbia University

Panel data are important for the development and testing of models of consumer behavior. Yet, panel data have a number of characteristics that affect the procedures used to draw inferences from such data. This session explores the problems involved in developing models using panel data by focusing on how these special characteristics of panel data must be recognized during analysis.

Attrition Bias in the Estimation of Econometric Models From Panel Data

Russell S. Winer, Columbia University

Scientific Advancement in Consumer Research: Some Problems Encountered When Using Consumer Panel Data

R. Dale Wilson, Batten, Barton, Durstine & Osborn, Inc.

*Decomposing the Correlation Matrix in Panel Data*John U. Farley, Columbia University
Donald R. Lehmann, Columbia University

Paper Session: INVOLVEMENT, LEARNING, AND ATTITUDES

Georgetown Room, Salon C

CHAIR: Donald J. Hempel, Univ. of Connecticut

An Exploration Into the Scaling of Consumers' Involvement with a Product Class

Peter H. Bloch, Portland State University

*Consumer Learning Through Experience: A Study and Experimental Paradigm*Joel Huber, Duke University
Terry Elrod, Columbia University*Measuring Consumer Attitudes Toward Alternative Check Verification Systems*David J. Barnaby, University of Tennessee
Richard C. Reizenstein, University of Tennessee
John W. Philpot, University of Tennessee

Discussant: David M. Gardner, Univ. of Illinois, Urbana

Special Topic Session: COGNITIVE APPROACHES TO CONSUMER
CATEGORIZATION OF PRODUCT/BRAND
CATEGORIES*Georgetown Room, Salons A,B*

CHAIR: Elizabeth C. Hirschman, New York University

A research area of increasing theoretical and strategic importance is how consumers develop perceptions of product/brand categories. The papers in this session present four theoretical frameworks from cognitive psychology that provide an explanation of consumer choice. Each theoretical framework is documented by a review of the relevant literature, and an attempt at empirical validation.

*Hierarchical Cognitive Content in Four Domains of Consumption*Elizabeth C. Hirschman, New York University
Susan Douglas, New York University*Usage-Situational Influences on Perceptions of Product Markets: Theoretical and Empirical Issues*

Rajendra K. Srivastava, Univ. of Texas, Austin

Product Perception as a Feature Matching Process

Michael Johnson, University of Chicago

A Means-End Model for Facilitating Analysis of Product Markets Based on Consumer Judgment

Jonathan Gutman, Univ. of Southern California

Paper Session: DIFFERENT INFLUENCES ON CONSUMER DECISION
MAKING*Potomac Ballroom, Salon D*

CHAIR: Betsy Gelb, University of Houston

*Mother's Attitudes and Perceptions of Children's Influence and Their Effect on Family Consumption*Mary Lou Roberts, Boston University
Lawrence H. Wortzel, Boston University
Robert L. Berkeley, Boston University*Four Situations and Their Perceived Effect on Husband and Wife Purchase Decision Making*Alvin C. Burns, Louisiana State University
Stephen P. DeVere, Louisiana State University*The Elderly Consumer: Past, Present, and Future*H. Lee Meadow, Virginia Tech
Stephen C. Cosmas, Virginia Tech
Andy Plotkin, Bridgewater State College

Discussant: E. H. Bonfield, Temple University

SUNDAY, OCTOBER 19, 1980

MORNING SESSIONS - 1

8:30 a.m. - 10:00 a.m.

Workshop: BEHAVIOR RESEARCH IN CONSUMER DECISION MAKING
AT A CROSSROADS

Georgetown Room, Salons A,B

CHAIR: Andrew A. Mitchell, Carnegie-Mellon University

The purpose of this workshop is to delineate the conceptual definitions and measurement procedures necessary for developing a theoretical understanding of consumer decision making. Each speaker addresses a particular research issue involved for developing such a theory of consumer decision making. The discussion will include the speakers and the audience.

Decision Strategies: Issues Surrounding the Dependent Variable in Decision Studies

James R. Bettman, Univ. of California, Los Angeles

Problem Framing Research

Peter L. Wright, Stanford University

Is Consumer Decision Making a Legitimate Offspring of Decision Making

J. Edward Russo, University of Chicago

Knowledge Structures, Production Systems and Decision Strategies

Merrie Brucks, Carnegie-Mellon University

Andrew A. Mitchell, Carnegie-Mellon University

Special Topic Session: CONSUMER DECISION MAKING: SOME
NEW DIRECTIONS FROM MANAGEMENT
SCIENCE

Georgetown Room, Salon C

CHAIR: R. Dale Wilson, Batten, Barton, Durstine &
Osborn, Inc.

Papers in this session concern research that interfaces the methodological orientation of the management or decision scientist with the behavioral orientation of the consumer researchers.

A Normative Model of Consumer Information Processing

David A. Aaker, Univ. of California, Berkeley

Michael R. Hagerty, Univ. of California, Berkeley

The Aggregate Effects of Induced Changes in Consumer Decision Structures

David J. Curry, University of Iowa

Jordan J. Louviere, University of Iowa

Michael J. Augustine, University of Iowa

The Cost of Thinking: Its Implications

Steven M. Shugan, University of Chicago

Discussant: Jagdish N. Sheth, University of Illinois,
Urbana

Paper Session: MEASURING THE EFFECT OF ADVERTISING

Francis Scott Key Room, Salon A

CHAIR: Dorothy Cohen, Hofstra University

The Effect of Recall on Belief Change: The Corrective Advertising Case

Neil K. Allison, University of South Carolina

Richard D. Mizerski, Federal Trade Commission

An Experimental Study of the Effects of Commercial TV Advertising and Pro-Consumer Product Test Results on TV

Emmanuel J. Cheron, Universite du Quebec a Rimouski

Jean Perrien, Universite du Quebec a Rimouski

Inquiry Response Rates, Cost and Revenue per Inquiry of Repetitive Print Advertising

Arch G. Woodside, University of South Carolina

Discussant: Robert F. Dyer, George Washington University

Paper Session: INFORMATION PROCESSING

Francis Scott Key Room, Salon B

CHAIR: Allan D. Schocker, University of Pittsburgh

Evoked Set Formation and Composition: An Empirical Investigation Under A Routinized Response Behavior Situation

Jacques E. Brisoux, Univ. of Quebec, Trois-Rivieres

Michel Laroche, Concordia University, Montreal

The Compensatory Dimension in Subjective Evaluation Processes: A Multimethod Validation

Ruby Roy Dholakia, Kansas State University

Developing an Instrument to Identify Individual Differences in the Processing of Pictorial and Other Non-Verbal Information

Flemming Hansen, University of Copenhagen

Neils Erik Lundsgaard, Frederiksberg Hospital

Discussant: George H. Haines, Jr., University of Toronto

BREAK: Coffee and Soft Drinks Lobby and Lower Levels

10:00 a.m. - 10:30 a.m.

Panel Discussion: REVITALIZING ATTITUDE THEORY AND RESEARCH: INCORPORATING IDEAS FROM COGNITIVE PROCESSING THEORY

Georgetown Room, Salons A,B

CHAIR: Jerry C. Olson, Pennsylvania State University

The purpose of this session is to present new theoretical ideas that may revitalize consumer attitude research. Drawing on cognitive psychology and information processing theory, the papers present perspectives that may be useful in explaining difficult conceptual issues in consumer attitude research, or in accounting for previously puzzling aberrations in the extant attitude data.

The Cognitive Structure Approach to Attitudes: A Review of Theoretical and Empirical Issues

Richard J. Lutz, Univ. of California, Los Angeles

A Memory Schema Account of Situational Influences on Attitude

Bobby Calder, Northwestern University

Belief/Knowledge Structures and Attitudes from a Cognitive Processing Perspective

Jerry C. Olson, Pennsylvania State University

Cognitive Processes in Attitude Formation and Change: Alternatives to Strict Cognitive Structure Explanation

Andrew Mitchell, Carnegie-Mellon University

Paper Session: CONSUMER SURVEY RESEARCH

Georgetown Room, Salon C

CHAIR: Philip G. Kuehl, University of Maryland

Investigating 'Income Refusals' in a Telephone Survey by Means of Logit Analysis

Robert A. Peterson, Univ. of Texas, Austin

Robert P. Leone, Univ. of Texas, Austin

Mohammad H. Sabertehrani, Univ. of Texas, Austin

The Effects of Salutation, Monetary Incentive and Degree of Urbanization on Mail Questionnaire Response Rate, Speed, and Quality

Linda L. Golden, Univ. of Texas, Austin

W. Thomas Anderson, Jr., Univ. of Texas, Austin

Louis K. Sharpe IV, Sharpe's Departmental Stores, Checotah, Oklahoma

What If Opinion Leaders Didn't Know More? A Question of Nomological Validity

Jacob Jacoby, Purdue University

Wayne D. Hoyer, Purdue University

Discussant: James H. Barnes, Jr., University of Georgia

Paper Session: THE CONSUMER IN THE RETAIL MARKET PLACE

Francis Scott Key Room, Salon B

CHAIR: Robert E. Wilkes, Texas Tech University

Retail Shopping Area Image: Structure and Congruency Between Downtown Areas and Shopping Centers

Michael J. Houston, Univ. of Wisconsin, Madison

John R. Nevin, Univ. of Wisconsin, Madison

Deviance and Dissatisfaction: An Exploratory Study

Michael K. Mills, Univ. of Southern California

Comprehensive Identification of Consumers' Marketplace Problems and What They Do About Them

F. Kelly Shuptrine, University of South Carolina

Gerhard Winglorz, University of South Carolina

Discussant: Donald Granbois, Indiana University

Paper Session: CONSUMER SATISFACTION AND BEHAVIOR

Francis Scott Key Room, Salon A

CHAIR: John Miller, University of Colorado

Testing Comparison Level and Predictive Expectations Models of Satisfaction

John E. Swan, Univ. of Alabama, Birmingham

Warren S. Martin, Univ. of Alabama, Birmingham

Complainers and Noncomplainers Revisited: Another Look at the Data

Kjell Grønhaug, Norwegian School of Economics and Business Administration

Gerald Zaltman, University of Pittsburgh

Effect of Satisfaction and Its Antecedents on Consumer Preference and Intention

Richard L. Oliver, Washington University (St. Louis)

Gerald Linds, Marsteller, Inc., Chicago

Developing Better Measures of Consumer Satisfaction: Some Preliminary Results

Robert A. Westbrook, University of Arizona

Richard L. Oliver, Washington University (St. Louis)

Discussant: Ralph L. Day, Indiana University

12:00 p.m.

CONFERENCE ENDS

Have a Very Successful Year

SEE YOU IN ST. LOUIS IN 1981!

TABLE OF CONTENTS

1979-80 Officers, Association for Consumer Research	iii
Reviewers for Paper Competition - 1980 Annual Conference	iv
Preface	v
1980 Conference Program	viii
Presidential Address	1
<i>William L. Wilkie, University of Florida</i>	
Presentation of the ACR Award	
<i>Harold H. Kassarian</i>	
"Fellow in Consumer Behavior" to John A. Howard and James F. Engel	6
<i>John Howard</i>	
Promotion in a Static Market	9
<i>James F. Engel</i>	
The Discipline of Consumer Research: Permanent Adolescence or Maturity?	12
PART I: THEORETICAL ISSUES	
A. EMERGING ISSUES IN LOW INVOLVEMENT THEORY	
<i>Clark Leavitt, Anthony G. Greenwald and Carl Obermiller</i>	
What is Low Involvement Low In?	15
<i>Richard E. Petty and John T. Cacioppo</i>	
Issue Involvement as a Moderator of the Effects on Attitude of Advertising Content and Context	20
<i>Andrew A. Mitchell</i>	
The Dimensions of Advertising Involvement	25
DISCUSSION PAPER:	
<i>Harold H. Kassarian</i>	
Low Involvement: A Second Look	31
B. ATTITUDE RESEARCH AND BEHAVIORAL INTENTIONS	
<i>Morris B. Holbrook, David A. Velez and Gerard J. Tabouret</i>	
Attitude Structure and Search: An Integrative Model of Importance-Directed Information Processing	35
<i>Paul W. Miniard</i>	
Examining the Diagnostic Utility of the Fishbein Behavioral Intentions Model	42
<i>David Brinberg</i>	
A Comparison of Two Behavioral Intentions Models	48
DISCUSSION PAPERS:	
<i>Paul R. Warshaw</i>	
A Discussion of Attitude Research and Behavioral Intentions	53
<i>Jeffrey E. Dames</i>	
Attitude Research and Behavioral Intentions: A Critical Review	57
C. INVOLVEMENT, LEARNING AND ATTITUDES	
<i>Peter H. Bloch</i>	
An Exploration into the Scaling of Consumers' Involvement with a Product Class	61
<i>Joel Huber and Terry Elrod</i>	
Consumer Learning Through Experience: A Study and Experimental Paradigm	66
<i>David J. Barnaby, John W. Philpot and Richard C. Reizenstein</i>	
Measuring Consumer Attitudes Toward Alternative Check Verifications	71

DISCUSSION PAPER:	
<i>David M. Gardner</i>	
Discussion: Involvement, Learning and Attitudes	76
D. CONSUMER SATISFACTION AND BEHAVIOR	
<i>John E. Swan and Warren S. Martin</i>	
Testing Comparison Level and Predictive Expectations Models of Satisfaction	77
<i>Kjell Grønhaug and Gerald Zaltman</i>	
Complainers and Noncomplainers Revisited: Another Look at the Data	83
<i>Richard L. Oliver and Gerald Linda</i>	
Effect of Satisfaction and Its Antecedents on Consumer Preference and Intention	88
<i>Robert A. Westbrook and Richard L. Oliver</i>	
Developing Better Measures of Consumer Satisfaction: Some Preliminary Results	94
E. COGNITIVE APPROACHES TO CONSUMER CATEGORIZATION OF PRODUCT/BRAND CATEGORIES	
<i>Elizabeth C. Hirschman and Susan P. Douglas</i>	
Hierarchical Cognitive Content: Towards a Measurement Methodology	100
<i>Rajendra K. Srivastava</i>	
Usage-Situational Influences on Perceptions of Product-Markets: Theoretical and Empirical Issues	106
<i>Michael E. Johnson</i>	
Context Effects in Product Perception	112
<i>Jonathan Gutman</i>	
A Means-End Model for Facilitating Analyses of Product Markets Based on Consumer Judgement	116
F. COGNITIVE PROCESSES	
<i>Rajesh Kanwar, Jerry C. Olson and Laura S. Sims</i>	
Toward Conceptualizing and Measuring Cognitive Structures	122
<i>Sanford L. Grossbart and Balusu Rammohan</i>	
Cognitive Maps and Shopping Convenience	128
<i>John G. Lynch</i>	
A Method for Determining the Sequencing of Cognitive Processes in Judgment: Order Effects on Reaction Times	134
G. THE EFFECT OF PRODUCT FAMILIARITY ON CONSUMER BEHAVIOR	
<i>Chin Tiong Tan and Ira J. Dolich</i>	
The Moderating Effects of Cognitive Complexity and Prior Product Familiarity on the Predictive Ability of Selected Multi-Attribute Choice Models for Three Consumer Products	140
<i>Larry J. Marks and Jerry C. Olson</i>	
Toward a Cognitive Structure Conceptualization of Product Familiarity	145
<i>Eric J. Johnson and J. Edward Russo</i>	
Product Familiarity and Learning New Information	151
DISCUSSION PAPER:	
<i>M. Joseph Sirgy</i>	
Product Familiarity: Critical Comments on Selected Studies and Theoretical Extensions	156
H. CONSUMER PERCEPTIONS	
<i>Albert J. Della Bitta and Kent B. Monroe</i>	
A Multivariate Analysis of the Perception of Value from Retail Price Advertisements	161
<i>John J. Wheatley</i>	
The Effect of Generic Products on Consumer Perceptions and Brand Choice	166

<i>Russell W. Belk</i>	
Determinants of Consumption Cue Utilization in Impression Formation: An Association Derivation and Experimental Verification	170
DISCUSSION PAPER:	
<i>Eric N. Berkowitz</i>	
Consumer Perceptions: A Discussion	176
I. PERCEPTION OF TIME AND CONSUMER BEHAVIOR	
<i>James McCullough, Douglas MacLachlan and Reza Moïnpour</i>	
Temporal Links Between Preference and Perception	178
<i>Philip E. Hendrix and Claude R. Martin, Jr.</i>	
Temporal Incongruity in Consumer Behavior	182
<i>Rebecca H. Holman</i>	
The Imagination of the Future: A Hidden Concept in the Study of Consumer Decision Making	187
DISCUSSION PAPER:	
<i>Wesley J. Johnston</i>	
Time and Consumer Behavior	192
PART II: METHODOLOGICAL ISSUES	
A. APPROACHES FOR DEVELOPING CAUSAL MODELS IN CONSUMER RESEARCH	
<i>Richard P. Bajocchi</i>	
Causal Modeling: A General Method for Developing and Testing Theories in Consumer Research	195
<i>Leonard J. Parsons</i>	
A Comparison of Causal Path and Econometric Modeling Approaches	203

Introductory Comments

[Before beginning my formal address, I would like to thank Kent Monroe, who acted as Conference Chairman for this event. Having had the pleasure of doing this several years ago, I can appreciate the substantial effort that he, his Program Committee, and his Arrangements Co-Chairmen, Gary Ford and Paul Bloom, have put into this conference.

I would also like to note that it gives me particular pleasure to be able to deliver a Presidential Address in Washington, D.C. ...especially in this election year. While thinking about what I might say, I began to appreciate the power inherent in the Presidency. As I stand before this distinguished assemblage, therefore, I am tempted to announce that I have ordered -- and there will in fact be -- a massive cut in government spending this coming year..... This will be coupled with a major tax cut for both businesses and individuals.

Inflation will end, and employment will rise..... Our savings rate will increase..... Productivity gains will be phenomenal.....

I am today placing our entire military forces on maneuvers in the Mid-East; this will result in immediate cessation of all hostilities in that region, and will shortly bring world peace and tranquility.....

Overall, I am pleased to announce that we shall shortly reach all of our goals in life, both individually and as a society.....

That is all I have to announce for today. Unfortunately, due to the press of world affairs, I will be unable to take questions at this time.....

Beyond the pleasure I get from being able to make such Presidential pronouncements, it is also a personal pleasure to return to Washington, D.C. for this occasion. I once lived here and came to feel great affection for the town. Some of you may not know, by the way, that Washington is considered to be the point at which the North and South of the United States come together. This special characteristic once led President John F. Kennedy to describe Washington as a city that managed to uniquely blend "old-time Southern speed and efficiency, with all the graciousness of urban Northern charm."

At any rate, unlike some other Presidential addresses this year, my speech today will not be mean..... Unlike some others, it won't be taken from note cards, and won't be memorized. Hopefully, though, it will be brief.]

ACR's Mission

My topic today deals with the central mission of the Association for Consumer Research, and how well we seem to be accomplishing this mission. After reviewing why ACR was founded, and how it proceeded at its start (Pratt 1974), I think that ACR's two key goals are quite clear:

- The pursuit and development of knowledge.
- A sharing in this pursuit.

The pursuit of knowledge is a basic goal for this type of organization; I intend to discuss it in more detail in the body of my speech. The explicit "sharing" goal is less typical, however. ACR was intended to be interdisciplinary in nature, and the pursuit of knowledge was intended to be accomplished across institutional structures. It was intended that persons in business, in government, and in academia should come together with this common goal,

each contributing significant perspectives and findings to the body of knowledge. As we all have seen, the pairing of these objectives presents a challenging task.

It turns out that our field's progress and problems have provided by far the most popular topics for past Presidential Addresses to this Association. They have been approached from several directions, including:

- The amount of work.
- The quality of work.
- Problems in theory and methods.
- Relevance of the work.
- Proper domain of our work.
- Some ethical issues in dissemination of our work.

Today, I would like to take yet another approach to this topic, mainly to ask in a broader sense, "When we, as an Association, assert that we want to pursue knowledge, what do we really mean?"

Overview of the Address

There seem to be three special issues involved here, and I have organized my talk according to these. First, there is the question of each member's personal choice whether or not to attempt to contribute to the development of knowledge. I would like to briefly address this in terms of "Individual Choice: Contribution and/or Participation."

Choosing to contribute to knowledge is no light matter. This is a point that I'd like to amplify upon in a second section, which discusses the literature on "The Meaning of Knowledge." In requiring that we possess knowledge before presuming to add to it, the choice of attempting to contribute suggests that past achievement is important.

In addition, of course, contributions will require future performance. The quality of such future performance -- or lack of same -- depends on one's willingness to work toward the goal. I would like to raise some basic issues here in the third section, entitled "Personal Acceptance of the Responsibilities."

On a personal note, because of the nature of this topic, there is a risk that this topic might seem pretentious and/or presumptuous. I want to begin by saying that I didn't choose this topic without reservations, and am not raising it as if I personally feel especially knowledgeable about it. I think, furthermore, that the real success or failure of this speech will actually depend on each of you, and how willing you are to deal with these issues at a personal level. They are important issues for our field, our Association, and for many of us as individuals.

Individual Choice: Contribution and/or Participation

As its base, the development of knowledge requires that each individual choose whether or not to undertake this effort. With respect to ACR, we should recognize that membership does not necessarily mean contribution to knowledge. For example, I expect that many of you have come to the conference solely for what you might take away from it, either to use in decision making, or because you simply find it to be of personal interest. There is certainly nothing wrong with this; one of our Associa-

tion's chief purposes is the dissemination of knowledge. On the other hand, we should not equate the roles of receiving knowledge and contributing to knowledge.

There are two key issues that I'd like to raise in this regard. The first issue concerns the motivation to contribute, while the second involves institutional barriers to such contributions. I expect that all of us can appreciate the personal motivations to contribute to knowledge, so will not attempt to delve into this area in any depth (whether this reflects insight or cowardice is not exactly clear to me).

At any rate, there is a book entitled The Cultivated Mind (Hodnett 1963) which bears on the motivation to contribute. I mention this book especially to this audience because Dr. Hodnett served both in academe and in business, gaining a background which should allow him to communicate well with almost all of us. His description of the "cultivated mind" seems an especially appropriate summary of why an individual might choose to attempt to contribute to knowledge. In brief, he asserts that the cultivated mind is distinguished by three qualities. It is a mind that is:

- Conceptual
- Discriminating
- Humane

The "conceptual" property refers to a mind that seeks understanding, desires to know, to know why, and is willing to conceptualize and speculate. The "discrimination" characteristic suggests that the cultivated mind is aware of and sensitive to value. The cultivated mind is "humane" in the sense that it is able to move beyond an obsession with self and a pervasive focus on its personal day-to-day affairs. The cultivated mind is thus capable of adopting a serious concern with mankind and the nature of the human existence.

Barriers and Facilitators

While individual motivation is basic to the personal choice to try to contribute to knowledge, it would be inappropriate not to recognize that some substantial barriers presently exist for certain of our members. The most obvious of these are institutional in nature. Most ACR members who work in business or government find themselves in roles which neither provide for, nor reward, attempts to contribute to general knowledge. This is a chronic problem, and well recognized by all of us. I certainly don't have a clear resolution for it, but would urge you to consider ways in which such contributions can be facilitated within the Association's rubric.

For example, I feel that our field is in need of more descriptive research on consumer markets and aggregate behavior. This form of contribution is likely to be readily available within business and government institutions, and would not require much additional effort to transmit to the field. Similarly, persons in business have closer and more specific contact with the actual consumer marketplace and purchasing behavior. This experience can provide a fertile ground for the development of insights into consumer behavior. These insights, while not achieving the rigorous standards of science, could provoke significant research investigations and refinements by others attempting to follow up on them. The Association's role would seem to provide vehicles for the presentation of these types of contributions, and to provide a receptive atmosphere for them. The stimulus, however, still needs to occur at the individual level.

With respect to other forms of barriers, I believe that the academic sector possesses some substantial constraints as well. These, however, are more informal in nature, and harder to pin down. I would like to raise them in a later portion of my talk.

What does it Mean to Add to Knowledge?

A Shared Heritage and Value Legacy

I mentioned earlier that a personal choice to attempt to contribute to knowledge is not an empty or minor gesture. The first perspective which I encountered in beginning to address the question was a realization that, by opting to assert a goal of "adding to knowledge," we have elected to join the thousands of men and women who have also sought this goal, and who have gone before us. In pursuing the goal, they have provided us with the knowledge which we now have available. In addition, they have passed on insights, philosophies, and warnings about the nature of the quest. It is sobering to realize the nature of the goal, and humbling to appreciate our significance in the larger picture.

The recognition of the others who have gone before us, and of those in other fields who currently share our broader goal, provides a useful perspective, an appropriate humility, and an important source of guidance for approaches to our development of knowledge. Before turning to consumer behavior matters, I would like to briefly share with you some things I've discovered in reading about the development of knowledge.

The Great Disciplines of the Mind: The Keys to Knowledge

In reading about the development of knowledge, it appears that there is a general agreement that certain disciplines are fundamental; additions to knowledge in any area must necessarily depend upon prior knowledge in these basic disciplines. In a sense, this suggests that before we can presume to add to knowledge, we must possess knowledge.

While there is not complete agreement on the exact number of basic disciplines of the mind, the following five receive great support:

- Mathematics
- Language
- History
- Logic
- Philosophy

Mathematics is the key to the natural and material sciences; it allows us to comprehend space and time, and to understand the basis of our existence. Language allows us to add human reason, and to communicate and transmit knowledge. History, which in some sense is our repository of knowledge, requires language for its basic material. Logic introduces the principles of reasoning, and employs the elements of language to arrive at new facts and new knowledge.

Philosophy, which can include logic, also transcends the narrow principles to provide us with consideration of norms and ideals for mankind. Within this area, metaphysics, the study of the first principles of being and reality, is perhaps the highest science. Within the melding of logic and philosophy, then, we are able to address the true (logic) and the good (ethics), and thus to approach some significant ideals of mankind. In addition (and beyond this framework) are the aesthetic areas, which aim to enhance our appreciation of the beautiful elements of life. Here are included art, music, and literature.

I think there are two distinct conclusions which derive from even an elementary consideration of these thoughts. First, the store of knowledge which humanity already possesses is awesome. One way to become more familiar with the scope of knowledge, if not with its depths and substance, is to examine the Propaedia of the Encyclopaedia Britannica. This volume wrestles with the question of how to conceptualize and organize "knowledge" in order to be able to summarize and present it in a complete and coherent fashion. In this regard, Mortimer Adler's remarks in that volume are especially illuminating.

The second conclusion that I reached pertains more directly to ACR and our topic today. The consideration of all knowledge places consumer behavior in an appropriate perspective; as a very small part of the puzzle, we should be open to appreciating that more developed areas might provide important insights for us. At the same time, though, it is important to see that we do belong in the puzzle, and this is reassuring. In joining the puzzle, however, we must accept that our additions to knowledge will come from, and depend upon, our mastery of the underlying disciplines or keys to knowledge -- the five areas listed above. It thus becomes appropriate for us to ask how well we have mastered these areas.

This is an uncomfortable question to raise. At the individual level, the most troublesome question might well be, "Can I contribute to knowledge if I do not possess mastery of any of the great disciplines?" Subsequent to this, one might inquire, "Can I contribute to knowledge if I am ignorant of several of the great disciplines?"

As a field of study, it would be worthwhile to assess which of these disciplines are relatively more significant for knowledge of consumer behavior, and whether some of the disciplines (philosophy leaps to mind) can be continually overlooked within our field. It is also important that we at least tentatively address the issues of whether sets of specialists, steeped in the application areas of one discipline, offer the most chance for advancing knowledge across the field of consumer behavior.

Trends

More broadly, recent trends are not especially reassuring on these grounds. For example, I recently noticed that only 12% of all college graduates are now matriculating in the traditional humanities areas of history, philosophy, language, literature, and the fine arts. This suggests a dwindling pool of persons available to offer these special forms of perspectives on our work in the future. Conversely, 90% of all scientists and engineers in the history of the world are alive and working today.

On a somewhat different note, the quality level at which the disciplines are being transmitted may be falling -- it is interesting to consider that there is no necessary reason that knowledge must increase over generations. For example, it is disturbing that the College Boards SAT scores, have just been reported to have declined for the 18th consecutive year. Whether we might wish to quarrel with the validity of these scores as predictive devices or not, they do make an effort to tap the level of understanding of three of the five disciplines listed above -- mathematics, language, and logic -- and these measures are falling.

In summary, I have found that reading about knowledge can provide a rich perspective on our field and our efforts. Before rushing to do research, it is reasonable to contemplate what most needs to be done. In addition, it is also reasonable to question our capability in certain areas. We should be willing to examine our training, our education, and our interests, and should be honest in appraising areas of weakness. When we find areas of weakness, moreover, it is appropriate to consider that attempts to build strength in those areas will pay longer term dividends than attempting to proceed as if these deficiencies weren't a problem.

Personal Acceptance of the Responsibilities

Not only does the choice to attempt to contribute to knowledge require a strong knowledge base, but it also brings with it a substantial set of responsibilities. Without a willingness to shoulder these, a decision to attempt to contribute to knowledge can be virtually meaningless.

In this regard, I would like to especially recommend The House of Intellect, a book by Professor Jacques Barzun (1959). In it, Professor Barzun delves into the requirements for -- and threats to -- high standards of intellect and contributions to knowledge. It is a powerfully written volume, and certainly does not attempt to please everyone. Because of this, however, it can serve as both an inspirational volume for some of us, and as a hard-line test of our personal willingness to take on the inherent responsibilities.

As to the responsibilities, there are two key types which stand out: effort and standards. With respect to effort, we should recognize that contributing to knowledge is a difficult and demanding task. It is work. At the same time, of course it brings benefits.

It is impossible to discuss effort, however, without also referring to standards, as these will directly affect the way in which effort is expended. As I will discuss shortly, a reallocation of effort is probably more needed than an increase in effort per se. Standards will provide a valuable resource in this reallocation of effort. One way to view this relationship is to recall that the choice to attempt to contribute to knowledge brings with it an implicit agreement to have one's work subjected to external judgments, which are expected to employ rigorous criteria. A most significant accompaniment to the development of scholarship -- and in some sense a measure of such development -- is the internalization of these standards or criteria, so that the contributor practices self-criticism at a high level before inflicting his or her output on the external world.

Standards of Quality

One type of standard relates to the inherent quality level of the work; how accurate, precise, valid, and/or insightful should a contribution have to be? Many persons (myself included) believe that our field suffers from the general acceptance of too low a quality standard. Knowledge is not advanced when a reader or listener must approach an offering with a legitimate scepticism as to its underlying veracity.

I believe that ACR, and our field more generally, would benefit from a consensus judgment that higher quality standards are in order. We should not be willing to adopt the minimal acceptable standards of our sister disciplines, or sister associations, but instead should strive for an absolute level of quality in our contributions.

I noted earlier that the issue of standards interacts closely with the question of effort. Here I feel encouraged that higher quality standards would not necessarily require more effort, although they would likely lead to reallocation of the effort. (This of course depends upon the underlying training and knowledge available to the individual; if this is insufficient to allow quality contributions, then remedial work seems clearly to be needed. Assuming that a reasonable background is available, however, it does seem likely that a reallocation of our effort would be fruitful.)

At present, it seems obvious that much effort is currently being expended fruitlessly, at least in terms of having impact on the body of knowledge in our field. For example, we have again this year failed to make a JCR/ACR Award in recognition of a doctoral dissertation article's contribution to knowledge in consumer behavior. None of us doubts that substantial work and worry was expended on dissertations in this past year, as in every year. Also, I don't doubt that some contributions did occur in each of these efforts. The degree of contribution, however, was viewed again to be insufficient to merit an award.

This is beginning to look like a chronic condition, and no one is pleased about it. While some minor adjustments in the process may be called for, it does seem inappropriate for us to lower our criteria in order to make an award; on the contrary, it would seem more appropriate

for doctoral candidates and their chairpersons to raise the criteria for doctoral dissertations.

Similarly, the acceptance rate at our major journals runs about fifteen percent each year. This means that six out of seven papers fail to meet minimal requirements for publication. Even allowing for adjustments to this figure to account for multiple submissions, lack of topic match-ups, etc., I am sorry to see such considerable effort involved in writing a manuscript go to such negative results. Again, wouldn't our field, and we as individuals, be better off if we simply raised the average quality level of our papers? Note that this could be done by lowering the number of papers, and expending more effort on the remaining projects.

As mentioned earlier, this would have to be accompanied by an acceptance and internalization of higher standards for our attempts to contribute to knowledge. The internalization process seems especially important, because often the external standards for publication are not high enough. Acceptance for publication shouldn't be seen as a vindication of our personal standards, nor as the primary purpose of our work. A preferable approach, I think, is for each of us to seriously examine whether we are adding to knowledge, broadly viewed.

Standards of Relevance

This brings me to my second issue under standards, which pertains to the "relevance" of our work. It is interesting to discover that "relevance" has always played an important role as a criterion for directing the pursuit of knowledge. In one sense, in fact, relevance can be viewed as the ultimate purpose of this pursuit.

However, the great thinkers have not chosen to define relevance in as narrow a sense as many of us apparently do. That is, they view relevance as a general measure of the fit or essential appropriateness of a project of the body of knowledge with which it is affiliated. Impact on the body of knowledge is one submeasure, but not the only one. Usefulness for immediate purposes, such as managerial or governmental decision making in our case, is another appropriate measure. Stress on this measure alone, however, can lead to a narrow conception of both the purposes of knowledge and of the most reasonable representations of phenomena within our field of inquiry. This can have deleterious impacts on basic forms of research, and might retard or even eliminate significant breakthroughs and contributions.

My particular concern in this area involves the feeling on the part of many persons in our field that consumer behavior is essentially an engineering discipline. If this position is advanced as a description of the current interests and motivations of most persons in the field, then I accept it as being accurate and appropriate. On the other hand, if this engineering orientation is advanced as a normative requirement or definition of the field of consumer research, I must emphatically disagree. Consumer behavior is an increasingly significant phenomenon in our world; it deserves description and understanding, independent of interests in improving, influencing, or otherwise benefiting from it.

Whatever the resolution to this issue, the more general problem of relevance is an appropriate standard for us to consider as individuals, and as a field. As individuals, this suggests that we should attend carefully to our substantive goals and motivations for each undertaking: What exactly am I attempting to add to knowledge with this undertaking? What questions need to be answered and will this potential project be able to answer them sufficiently well? If not, can it be revised or refined to do so? If not, should a different question be pursued, or should a new undertaking be substituted?

Although it sounds trite, I think that we typically don't spend nearly enough mental effort on exactly these questions. I would point to this deficiency as one of the major causes of rejection rates at our journals and conferences, and as a major reason that persons looking for

application help in decision making tend to openly complain about the "irrelevant" work done by academics in our field.

In concluding this discussion of responsibilities, I think that the major implication is that each of us would benefit from a hard, objective assessment of both our willingness to accept the inherent responsibilities, and of the extent to which our preliminary efforts are likely to meet the required levels of quality and meaning of the problem at hand. This is inherently a personal, individual process. It can be greatly assisted, however, if external feedback and/or yardsticks are integrated into that process. By raising our standards as a field, I believe that the individual's decision making in this area would be both enhanced and rewarded.

Conclusions and Closing Remarks

As I indicated at the start, I hope that the most significant conclusions from this talk will occur at the individual level, in the form of personal contemplation and decisions about our individual roles in the field. I also expect that these conclusions will differ substantially within this group, and I think that this is quite appropriate. Therefore, I am left with only the possibility of forwarding some of my conclusions from a more aggregate, association point of view. I hope that you will accept these in that light.

Really a Small Group

First, I think that if we were to honestly apply the three criteria in this speech -- possessing knowledge, choosing to contribute, and accepting the responsibilities -- to our field as a whole, we would have to conclude that the number of people actively contributing to knowledge is considerably smaller than the number of people affiliated with this area. I would not expect consensus on the underlying knowledge requirements in regard to the five great disciplines of the mind, but certainly this must impair our ability to develop knowledge. Further, it is obvious that a number of us have chosen to participate, but not especially to contribute. This leaves a smaller group who may have tentatively made the choice to attempt contributions.

Insufficient recognition and/or acceptance of the concurrent responsibilities, however, remains a serious barrier to the actual realization of contributions. It is my impression that a number of persons find this barrier inconsistent with their personal motivations, and decide to avoid it. This takes another major cut into the ranks of contributors, leaving us with a fairly small group, especially when contrasted to the wide range of issues in the field of consumer behavior.

ACR needs More Contributions

I think this point is clear, when we consider how much work remains to be done, and the pace at which we are overcoming areas of ignorance. My comments earlier on the desirability of more contributions from business and government sectors are pertinent here as well.

In addition, there are some closing perspectives I wish to raise regarding the academic sector. I would divide these into two categories.

The first pertains to the "older, established" contributors, most of whom are affiliated with academic institutions. To this group I wish to offer no recommendations. In the spirit of my topic, I wish to pay my respects to you, as you are the people who have brought the field this far along. You know what high standards mean, and you know the effort required to produce contributions to knowledge. I wish only to transmit the message that the field will benefit from your decisions to stay active,

to continue to contribute, and to act as role models for others who wish to make contributions.

There are several points I would like to offer for the "younger, not-quite-yet-established" members. First, in evaluating your decisions to decide to contribute to knowledge, please take the discussions of accepting responsibilities in a most serious way. Many -- and probably most -- persons have not really done this, and most institutional entities in our field do not really require it. As a result, you may find little overt guidance towards internalization of the standards and effort-levels which really ought to be your goals.

Unfortunately, if you adopt what appears to be "accepted" standards, together with diffuse and unexplicated goals, the chances for "success" in academia are sharply curtailed. In addition, but perhaps less obvious, the chances of your making contributions to knowledge drop significantly. For many persons, it appears that this combination of factors leads to a later conception that one is merely "playing a game," and that the deck is stacked against the player. Substantial time, efforts, and emotional costs may then be expended in attempting to outfox the opposition and obtain "another pub" for the resume. If we would step back a bit and abstractly view the needs of our field, we could easily see that this system is misdirected.

In fact, however, the more straightforward system is the better and assuredly more rewarding to pursue. The leaders of our field recognize its need for contributions. The established contributors in the field are able to recognize new contributions, and generally await the appearance of same. Unlike the perceptions that I know that many of you either hold or have heard, this is not an "in-group" association, nor is it a "private club" running the field. In fact, this association was born, as I understand it, in large part to avoid these very characteristics. In short, the field wants to look positively on your work. It needs your work, and it knows it.

As I listen to myself saying this, I realize that it may not be very convincing to you, especially if you already hold the opposite view. Perhaps an example might be useful in this regard, because it strikingly demonstrated to me the field's real receptivity to quality work. One such situation occurred about five years ago at the ACR Conference, in a particularly negative setting. In brief, we had been involved in an all-day special topics session, with a reasonably small group -- maybe 30 or 40 people -- with a sincere interest in the subject. By the end of the day, we were hot, tired, and generally in a bad mood. As the papers went on, criticism became more severe. By the time the final paper was scheduled, most of us, I think, were quite ready to get to the football game where we could take out our frustrations. The last thing in the world anyone wanted to hear was a mediocre or bad paper.

Unfortunately, the last speaker had to walk into this situation. He was not a "big name" in the field; to the contrary, he was a young academic, trained at not one of the major prestige universities, and he was just beginning his career. As he started to speak, some of the testier members of the audience began to sound him out on various detailed issues of the topic. If he had failed to deal with these questions adequately, they would have felt comfortable in dismissing the remainder of his effort, and probably appropriately so. I don't know if I have vividly portrayed the whole context, but it surely was a severe test.

However, he stepped up and did a superb job. He handled the questions, sometimes adding additional issues which hadn't been included. He demonstrated an awareness of the key work on the topic, and an interest in improving the conceptualization and research in the area. In short, he gave a fine talk, and made a contribution with it.

My point in relating this episode involves what happened next. As soon as the discussion ended, I watched as leading scholars from three or four of the major in-

stitutions in the country walked up and introduced themselves. In the space of a half-hour, he had moved dramatically upward in their evaluations. He later moved to one of the top schools in the nation, where he is now a veteran on the faculty.

The moral of the story is two-fold. First, this didn't happen easily. This man had to be able to meet a relatively rigorous set of standards to be viewed as making a contribution. This had required long hours of work on his part, and a sincere interest in the topic. He had already put in those hours and made that commitment long before arriving at the ACR session. Second, when others recognized the contribution, they were pleasantly surprised, interested in discussing the topic further with him, and wanted to encourage him to continue his work. This is what our field is really about, and I hope that the younger members will recognize it and appreciate it.

Summary: The Goal

In this speech I have ranged over a variety of issues, and have attempted to discuss both pragmatic and abstract questions. I hope that these comments may stimulate some further consideration of "what it means to add to knowledge" by all of us. In closing the substantive portion of this talk, I would like to quote Dr. Barzun, as he summarizes his discussion of the House of Intellect:

"These considerations make only more imperative the safeguard of the master virtues of Intellect. They are, once again: concentration, continuity, articulate precision, and self-awareness. Intellect needs the congregation of talents spurring one another to high achievements by the right degree of proximity and intercourse; it needs the language and the conversation that maintain its unity like a beneficent air; it needs precision to dispel the blinding fogs of folly or stupidity; it needs self-awareness to enjoy its own sport and keep itself from vainglory."

Closing Comment

Given the nature of the topic I chose, it is almost necessary that we be dissatisfied with the level of our work, and with the progress we have made. It would be inappropriate, however, for me to close this talk on that note. Yesterday it was mentioned that ACR grew out of an initial conference at Purdue, then took shape at a subsequent meeting at Ohio State. The shocking fact is that this started only 14 years ago! In this very short period of time, we have come a long way, and can be proud of our progress.

On a personal note, I would like to close by saying that I am truly appreciative that you were willing and saw fit to elect me as a President of ACR. I have enjoyed the chance to serve during this past year, and to have seen firsthand many of the finer elements of the Association and its membership. Thank you very much.

PRESENTATION OF THE ACR AWARD:
"FELLOW IN CONSUMER BEHAVIOR" TO JOHN A. HOWARD AND JAMES F. ENGLE

Harold H. Kassanjian, University of California, Los Angeles

I consider it a great honor to have been selected to make these first awards for "Fellow in Consumer Behavior", and to share this podium with two unique scholars. For each, in his own way, has had a long term significant impact on the field of consumer behavior. And this award was created to honor just that type of contribution, a long term, major, scholarly impact.

The idea of such an award was not a rapid decision by the Board of Directors. Discussions concerning an ACR award were initiated as early as under the presidency of Joel Cohen, now almost a decade ago. Over the years, numerous individuals were involved and committees appointed to consider the suggestion. It was felt that the fellow award should not be based simply on longevity in the field, or only because a given colleague was well known. It was not intended to be given for a single work, article, book, or monograph. Unlike awards given for "the Best Article", a single major scholarly work would not necessarily qualify for this award. Also a stream of research carried on for several years that may have had an impact on the field might well not qualify for the award.

The status of "Fellow in Consumer Behavior" was to be reserved as recognition to the individual for scholarly contributions spanning not just a few years but rather a distinguished long term commitment.

After several years of deliberation on goals and procedures, the final decision was made that there should be a selection committee composed of a chairman appointed by the president of ACR, and as committee members, the three immediate past presidents of the association. This, it was hoped, would represent a broad spectrum of interests with a committee regarded highly enough to have been elected by the membership as president over a three year span.

The decision of the committee was to be unanimous, for if consensus could not be achieved, the award should not be given that year. The decision was then to be presented to the Board of Directors for confirmation by a 75% affirmative vote. The award will not become a routine event given each year to whomever is still around. There will be no award next year, for example. Also a three year "sunset" provision was enacted to review the program.

The first year, the award committee consisted of James Myers, chairman, appointed by the then president of the association, Keith Hunt. The other members, the three immediate past presidents, were Jerome Kernan, David Gardner and myself. This committee solicited nominations from the membership but under no conditions felt obligated by a vote count or obligated to pay attention to the fact that some potential candidates were or were not nominated. For popularity was not to be one of the criteria. Although enthusiasm by colleagues might be considered, it was clearly not sufficient.

The final decisions were unanimous and enthusiastic. The Board of Directors enthusiastically and unanimously approved the nominations. From zero to three awards may be made each year. The first year, two individuals were thus selected.

¹Written while visiting professor at the Copenhagen School of Business Administration and Economics, Denmark.

John A. Howard

The first is Professor John A. Howard, Columbia University. Professor Howard did not start his career in consumer behavior. As you well know, consumer behavior as a field of scientific endeavor did not exist at that time.

His bachelor's degree in economics was from the University of Illinois in 1939 and his Master of Science in Economics in 1941. He received his doctorate from Harvard University in 1952 with a dissertation on British Monopoly Policy, prepared while at Oxford University in England.

Professor Howard's first teaching assignment was at the University of Illinois. From 1950 to 1958 he was professor at the University of Chicago, then for five years at the University of Pittsburgh. Since then he is professor at Columbia University.

In 1959 he was commissioned by the chairman of the Scott Paper Company to investigate the need for basic research in marketing. That study led to the establishment of the Marketing Science Institute. He has been a consultant to the Department of Commerce and to the Federal Trade Commission. His work at the FTC led to the acclaimed monograph, Advertising and the Public Interest, co-authored with James Hulbert. In 1975 he was awarded the Paul D. Converse award for "contributions to theory of marketing and buyer behavior" for four of his publications:

Marketing Management, 1963
Marketing: Executive and Buyer Behavior, 1963
Marketing Theory, 1965
The Theory of Buyer Behavior, 1969,
with Jagdish N. Sheth.

As with many other early pioneers in this field, Ford Foundation money was to take on a significant role in Professor Howard's career. Today many of us are unaware of the pivotal role the Ford Foundation had played. In their effort to up-grade business schools, marketing scholars were encouraged to incorporate the behavioral sciences, mathematics, and other basic scientific disciplines into their research, teaching, and thinking.

In 1960, Howard was commissioned by the Foundation to do a two-year study on the state of knowledge in Marketing. The results of that study led to the monograph, Marketing: Executive and Buyer Behavior. This was the embryo from which Howard and Sheth's, The Theory of Consumer Behavior was to emerge, and in fact that monograph was quite influential on the development of the Engle, Kollat and Blackwell model as presented in their text.

In turn, the roots of Executive and Buyer Behavior appeared earlier yet in Howard's intellectual career. For in the first edition of his Marketing Management textbook, Howard discussed buyer behavior from a behavioral science perspective. His very first model of the consumer was an adaptation of Clark Hull's learning theory to behavior found in the marketplace. By the time of the second edition in 1963, this view had been expanded to almost a chapter length discussion of behavioral science in marketing. And tangentially, another new topic was given an embryonic introduction - mathematical models and stochastic learning theory. This work was expanded in the

monograph, Marketing Theory, in 1965 and culminating, as already mentioned, in The Theory of Buyer Behavior in 1969. Part of a one-half million dollar program at Columbia to build, test, and apply a theory of consumer research, this stream of activity led to several doctoral dissertations as well as to follow-up research and conceptualization by Howard and his colleagues. This work led to numerous papers and the monograph, Consumer Behavior: Applications of Theory in 1977. Unlike so many builders of grand theory, Howard has been most interested and involved in testing his models. And this may have been his major accomplishment - the one he can be quite proud of. But, Howard played another role in Consumer Behavior - a role, that now, few may recognize. Howard was not a renegade, he was not a rebel with a bag full of new gimmicks called behavioral science and learning theory with which to dazzle the staid establishment in marketing. For Howard was part of the marketing establishment - in a time when marketing consisted of a bit of economic theory, wholesaling, transportation, etc. New fangled ideas were not easily being accepted into the establishment and marketing people simply tended to be hostile to behavioral science and mathematics. Programs at the American Marketing Association were typically not available to those interested in the behavioral sciences. Papers on psychological topics or even landmark work on stochastic models were generally not acceptable to the journals and programs of the day.

John Howard was a member of that establishment - he had authored a widely used text in marketing management, and yet he was willing to integrate some of these new ideas into the field and to encourage unorthodox research. If for nothing else, it is for that role of creative innovator, open-mindedness, scholarly rigor and respectability, and a leadership role of which he may not even have been aware, that we are in debt to Professor Howard. The rest of us could point to the work of Howard to support the introduction of basic behavioral research into the business schools. For here was a respected member of the establishment using the term buyer behavior.

Fittingly, and with humility, Professor Howard was selected as one of the first two recipients of the "Fellow in Consumer Behavior" award, (and I quote), "For focusing attention on the importance of consumer behavior and for pioneering work in conceptualizing consumer decision making". Professor Howard, we thank you.

James F. Engle

The second person to receive the first awarding of the "Fellow in Consumer Behavior" recognition is Professor James F. Engle. Professor Engle is from another academic generation than his co-recipient and revolved in a different orbit. Not trained in economics and not a member of the establishment at the time, Engle was the beginning of a new breed. He entered Drake University in 1952 with an interest in music and a drama scholarship only to switch his major to marketing because several of his friends were majoring in marketing. And so, a career was launched.

Under the influence of Professor Martin Zober, one of the early people who felt that marketing should take the consumer seriously, Engle took electives in psychology, social psychology and cultural anthropology - something mighty unusual at the time.

Turning down attractive fellowships for graduate work from other Big 10 Universities, Engle matriculated at the University of Illinois at the end of an era of ferment and excitement - the time of P. D. Converse, Huey, Hugh Wales and the young new kid on the block - Bob Ferber. Under the influence of Wales and the work Wales and Ferber had been doing on motivation research, again Engle turned to social psychology for his minor area and to a

methodological study of motivation research for his dissertation.

His first professional position was to be at the University of Michigan where he began the integration of the behavioral sciences into an advertising course - the same course, by the way, where other behavioral types throughout the land were being relegated. And it was here that he conceived his Promotional Strategy book with Wales and published his laudatory work on cognitive dissonance. For its time, this paper was a fine piece of empirical research integrating social science concepts and methodology into advertising and marketing. That, along with the promotion book and a paper on perception were among the early attempts at borrowing concepts, middle-range theories, and methodologies from psychology and applying them to consumer behavior in the marketplace.

But, at his university, as in so many other business schools, this type of work and this type of research thrust was neither appreciated nor understood. It did not mesh with the established norms of academic activity. The time had come to move to The Ohio State University. Here, within a short time, a critical mass, a symbiotic relationship, emerged as a consumer behavior group was formed by Engel, Kollat and Blackwell and the contributions of a graduate student, Larry Light. The culmination of that effort was the first true textbook in the field, Engel, Kollat and Blackwell's consumer behavior trilogy. Now in its third edition, and the fourth being conceptualized, that text has unquestionably become the standard work in the field by which all other texts, course outlines and course content are compared and categorized. Throughout the land, courses in Consumer Behavior were introduced with the EKB Table of Contents as the outline. What was left for other authors and publishers of texts was to attempt to carve out a small market share below or around the EKB positioning, for it is still the standard work in the field.

But the Engel contribution is far more than an article on dissonance, a paper on longitudinal analysis, a study on the use of self-medication drugs, or the co-authoring of a text, or any of his 60 other papers, books and articles. For the name James Engel, in many ways is synonymous with the Association for Consumer Research and the field of consumer behavior.

Perhaps the key turning point of the academic discipline of consumer behavior can be traced back to a meeting at Purdue University in 1966. King, Bass, Pessimeir and others at Purdue invited the promising young men in the field of marketing to attend a week-long conference. Engel and Light presented a paper on cognitive dissonance and a model of consumer behavior - the nucleus of the EKB model. It was here that various people interested in consumer behavior began to realize that throughout the land, there were others with similar interests and experiences and on-going research. For this was the debut, the debutante ball, not only for Engle and others of similar vision but for the field itself. Consumer Behavior need not be the ugly duckling of marketing but rather might be an interdisciplinary field of scientific endeavor in its own right.

In the end, it was Engle who did not let the fledging swan wilt but with his colleagues nursed and nurtured it to its outgrowth - the 1969 Ohio State Workshop on Consumer Behavior (three dozen people meeting with a thrill of intellectual companionship that few had experienced before - under the guiding hands of James Engle).

When this association was formed that Saturday afternoon, with everyone tossing in a ten dollar bill to get it launched, I think I shall never forget glancing at Jim Engle. He had just smiled at a colleague - I believe

either Kollat or Blackwell - a smile I perceived as a self satisfied grin of accomplishment - proclaiming with his eyes, "we pulled it off, we launched the organization".

Yes, professor, you pulled it off. You fathered, you wet nursed an interdisciplinary field of scientific endeavor. And now, for his intellectual stimulation, for his writings and research, for his leadership, for his "significant impact on scholarly work in consumer behavior", the Association for Consumer Research presents him with the award, "Fellow in Consumer Behavior", (and I quote) "in recognition of his singular contribution to the systematic study of consumer behavior". Professor Engle, we thank you.

PROMOTION IN A STATIC MARKET*

John Howard, Columbia University

Introduction

I am deeply honored to receive this symbol of the esteem of my colleagues. It is one of the finest achievements that I could hope for. As my response in accepting it, I would first like to make a brief assessment of the state of knowledge in the field of consumer behavior.

State of Field

Remarkable progress has been made since about 1955 in developing theory that has relevance for practice. Let me apply this pragmatic definition of progress--creation of theory relevant for practice--and briefly evaluate research on each of the stages of choice that we, economists and psychologists have found useful (Howard, 1977) and especially now that Jim Bettman and Michael Zinns (1977) have given some empirical legitimization to that typology.

In the most common case--a buyer confronted with an unfamiliar brand in a familiar product class (limited problem solving)--research has gone exceedingly well by my pragmatic definition of progress. I need only cite the recent splendid technologically-oriented review by Shocker and Srinivasan (1979) which was possible only because of theory development.

Research on the case of a buyer confronted with an unfamiliar product class (extensive problem solving)--innovation--is going well. We have broken out of the confines of the rural sociologist's work in diffusion, which emphasizes the social processes and individual differences among buyers. Instead, we are focusing upon information processing (Bettman 1979) and upon values as the source of choice criteria (Howard 1979). Also, especially encouraging is Peter Wright's (1980) fascinating recent experiment on product class advertising.

Research on the third case--a buyer facing a familiar brand in a familiar product class (routinized response behavior)--however, has been disappointing, even though economists under the stimulus of Stigler's seminal article have also been lending a hand (Rosen 1976). I would like to address it at greater length.

Obvious Contradiction of Theory

Our RRB theory seems to me to be beset with a serious contradiction. Stated most baldly, our behavioral theory predicts that in a stable market consumers will learn about the array of brands and zero in upon the most preferred brand. This loyal behavior, then, will continue ad infinitum unless a change in the market occurs. Our prediction implies there should be no advertising because there is nothing to communicate.

*Paper given before the Annual Meeting of the Association for Consumer Research in reply to the honor of being appointed a Fellow in Consumer Behavior, Washington, D.C. October 17, 1980. I am grateful to Professor Wilfried Vanhonacker, my colleague, for his splendid comments on the paper.

But if we look around at the real world, it seems to me that we see far more contradictions of this prediction than we see consistencies, e.g. cigarettes before health warnings triggered a spate of minor product innovations. This conclusion, of course, assumes that managers spend their advertising budgets wisely. From the decision net studies of a number of executive decision processes in the early 1960's, I believe that for short-term decision-making this assumption is reasonably valid (Clarkson 1962); Howard and Morgenroth 1968). Also, I am ignoring the possibility of "reminder promotion" which tells the consumer, in effect, that the product class is available, which can cause shifts among product classes such as in food where there is flexibility across product class boundaries.

This contradiction of our theory has troubled me for several years. Not only is it blatantly obvious, but it involves a considerable proportion of our economy. Hence, whether our theory fits the facts in this case makes substantial difference. Further, we must remember that the success of our theory in the most common case--LPS--came as really quite a surprise to most of us. I was not nearly as confident that consumers used information in their buying as my words indicated. Because of my general skepticism, our failure in the simplest case--RRB--has had a profound effect in creating serious doubts in my mind about our entire venture into understanding the consumer.

In fact, in my concern about the contradiction, I have felt somewhat akin to Professor Weyl, the great mathematician who, in 1946, wrote, "...we are less certain than ever about the ultimate foundations of (logic and) mathematics... Like everybody and everything in the world today we have our 'crisis'... Outwardly it does not seem to hamper our daily work, and yet I for one confess that it has had a considerable practical influence on my mathematical life; it directed my interests to fields I considered relatively 'safe' and has been a constant drain on the enthusiasm and determination with which I pursued my research work."

Now, having recited my tale of woe, let me take a more positive view and conclude that the field even in the area of routinized response behavior is in better condition that I had thought.

Contradiction of Theory Removed

In the 1960's, I became interested in Daniel Berlyne's work on the effect of novelty in esthetics and other areas of human behavior. Out of it I developed the ambiguity-arousal hypothesis which some of you might remember from the book with Professor Sheth (1969, pp. 202-220).

This hypothesis predicted that once consumers have zeroed in on their preferred brand in a stable market, they would, after a period of brand loyalty, become bored and shop around trying some alternative brands that are more novel, more interesting, and then again zero in on a preferred brand. A cyclic pattern of behavior would result: stability of brand loyalty, instability, stability, etc.

Not being able to think of an effective way to test it, I had forgotten all about it. Then, three years ago, I received in the mail a monograph on testing stochastic choice models done as a dissertation at Rotterdam University in Holland.

The author, B. Wierenga (1974), creatively develops the concept of "pool size." In this way his work went beyond that characterizing the stochastic choice research prior to the late 1970's. By defining "pool size" as the number of different brands bought in the last 10 purchases, he makes pool size the critical measure of behavior.

He uses three product classes of low-priced, frequently-purchased items to determine if the cyclic patterns predicted by the ambiguity-arousal hypothesis could be said to characterize the behavior of consumers. The products were beer, margarine, and a third unspecified item called "fopro." At least three of the brands for each product were national brands distributed over Holland as a whole and promoted by newspapers, television and radio on a national scale. The information was collected from a 2000-member commercial purchase panel for the two year period 1967 and 1968.

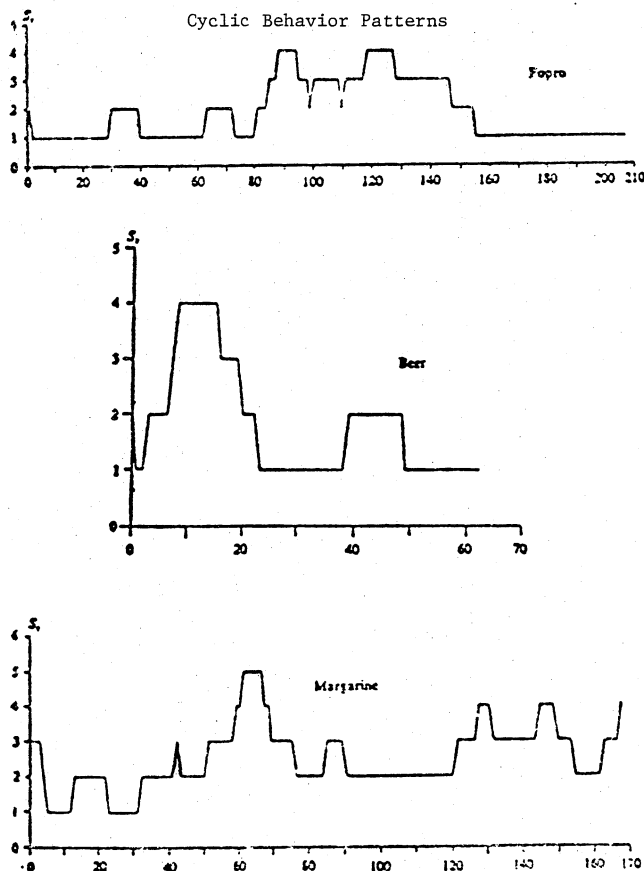

To be more specific, I will describe his method first as applied to the purchasing of a single family, but a different family for each product, as shown in Figure 1. S is the poolsize measured on the vertical axis and it is the number of different brands bought by the family in its last 10 purchases. Of course, t is time. At purchase S_t for fopro, for example, the poolsize is 2, as you will note. In the purchase sequence t-9, t-8, t-7, t-6, t-5, t-4, t-3, t-2, t-1, t, two different brands were purchased by this family. S was immediately reduced, however, to one particular brand because at purchase S_{t+1} , over the purchase sequence t-8, t-7, t-6, t-5, t-4, t-3, t-2, t-1, t and t+1, the family bought the same brand. This single brand purchasing continues with fopro for 28 purchases, at which time another brand, other than that originally bought, was purchased, which brings the total to t=29. Figure 1 implies that during the next 9 purchases, the pool will contain at least two brands and it is possible that a consumer in one time period completely switches to the new brand. If he did, the pool size of 2 lasts for exactly 9 purchases. After 10 purchases (t=39), the pool size returns to 1, which indicates that no further purchase of the new brand was made while no other brands were tried in the meantime. After that, there is a period of no brand-switching which lasts for 23 purchases (t=62). Again, an incidental purchase of a different brand occurs followed by a short rest (t=80). Then a period of intensive brand-switching begins where the pool size increases to as much as 4. Following this turbulent period, the family seems to have made its choice and continues for a long time buying the same brand.

As you see in Figure 1, fopro and beer show each one period of extreme search. "Search" is defined as when, during a certain period, the buyer tries a number of different brands before settling on a particular brand as contrasted with a straightforward switch from one favorite brand to another favorite brand. Margarine exhibits two such periods. Also, fopro was much more inclined to single brand periods than the other two products.

In Figure 1 we have seen in single households evidence of cycles where, after periods of intensive search, the family alternates with periods of continuous buying of the same brand within a period but not necessarily across periods. A similar picture emerges when all 2000 households are thrown together.

Unfortunately purchase patterns cannot be shown diagrammatically for more than a single family. Instead, they can be described by using the range of difference between the maximum and minimum of pool size over all families. The results for families buying two or more brands are shown in Table 1. Families that bought only one brand during the two-year period of the data are excluded because we want to show the variation in switching required to conform to the search-loyalty cycle. These continuous repeat

Figure 1

purchasers constitute roughly a fourth (fopro = 28%, beer = 27%, margarine = 16%) for all three brands.

As you can see in Table 1, where RANGPLZ means range of variation in pool size, a substantial difference in levels of switching activity occurred. In fopro, for example, 2.69% exhibited no variation, while 46.69% showed a variation of 1. This is consistent with the search-disloyalty cycle concept. Specifically, the pool size is not constant but has periods of low values and periods of high values.

Table 1

Relative Frequency of Range of Values for Households with More than One Brand

RANGPLZ	Fopro	Beer	Margarine
0	.0269	.1204	.0190
1	.4669	.5055	.3814
2	.3223	.2582	.2975
3	.1157	.0875	.1745
4	.0475	.0241	.0738
≥ 5	.0207	.0044	.0537
	1.0000	1.0000	1.0000
Number of Households with ≥ 2 brands	484	457	894

But we should ask ourselves whether these patterns of cyclic behavior could have been the result of promotion or other marketing activity instead of the ambiguity-arousal hypothesis? If we examine the pool sizes of different consumers at a given point in time, we find they

are different. They are not low and high together. If the source of the cyclic pattern was a common marketing activity, the lows and highs of different consumers would tend to occur together in time.

But once they have decided to shift, marketing effort does appear to make a difference in which way they shifted, to which brands. Specifically, the start of search is often associated with changes in price, deals, shop where bought and unit-size bought, which supports the notion that promotion is justified as implied by the ambiguity arousal hypothesis. The absolute number and proportion of each of these promotional events associated with brand switches are seen in Table 2.

Table 2

Relative Occurrence of Different Types of Concomitant Events of Search-Initiating Brand Switches

	Fopro		Beer		Margarine	
	abs*	perc**	abs	perc	abs	perc
Number of brand-switches observed	76	100	34	100	211	100
With concomitant event:						
Price change	29	36.7	5	14.7	141	66.8
Deal	6	7.6	0	0	18	8.5
Shop change	50	63.3	18	52.9	115	54.5
Unit-size change	33	41.8	22	64.7	-	-
None of these	4	5.1	5	14.7	26	12.3

* Absolute

** Percent

Additional support was also given the cyclic hypothesis in this study in that the linear learning model, which implies cyclic behavior, gave the best fit to the data among the various stochastic models (Wierenga p. 184).

We must be careful, however, in generalizing the results of the Dutch study to the United States. My colleague, Professor Wilfried Vanhonacker, informs me that most American studies have typically found zero order probability and with a pool size of about 4, although with some exceptions.

What I conclude is that hidden within this high shifting in the American market is a substantial number of customers exhibiting cyclic behavior as predicted by the ambiguity-arousal hypothesis. Not as high as the roughly 80% in Holland, but enough to justify the marketing effort we see in stable markets in the United States. This will, of course, have to be verified and I throw it out as a challenge to fellow researchers.

Conclusion

This finding renews my faith in progress in our work now that I have been provided an answer for the one gnawing question that has plagued me for years. It has implications for both private and public policy. I have emphasized the private policy, but its public policy significance can be still greater. It can be at least a partial answer to charges of pseudo-differentiability and shared monopoly, for example.

THE DISCIPLINE OF CONSUMER RESEARCH: PERMANENT
ADOLESCENCE OR MATURITY?

James F. Engel, Wheaton Graduate School

Abstract

It goes without saying that it is a high honor to be named as one of the first two Fellows of the Association for Consumer Research. It is gratifying to hear that voice of colleagues saying, "we think you're OK," and all I can do is to express a heartfelt thank you. This makes all of those years of digging in the trenches worthwhile.

I am grateful also for the opportunity to reflect on the state of the art in this polyglot discipline. This will not be the somewhat tedious methodological and conceptual critique of the type previously voiced by Jacoby, Kassarian, Cohen, my colleagues and me, and others. While these have their role, it is my intent first of all to look backward focusing on some signs of progress along the way. Indeed, it is fair to say that our field has grown from crawling infancy to a fairly healthy state of adolescence in a short period of time. My fear, however, is that we are destined to permanent adolescence unless we do some serious stocktaking. Therefore, the primary purpose of this paper is to stimulate careful analytical assessment in the hopes that we can finally emerge as a discipline showing some much-needed signs of maturity.

The Road to Respectability

I have always dated the birth of consumer research as a serious discipline in and of itself back to the late 1950's. Obviously the roots go back much further than that, but this period marked the appearance of a handful of "marketing types" who possessed at least some training in the behavioral sciences. These names are well known to most, and I happened to be one of them pretty largely by luck and by accident.

Our early work, by and large, consisted of the "theory of the month club," to borrow one of Jack Jacoby's apt phrases. We worked independently at first and frankly were on a fishing expedition throughout the behavioral sciences. This soon began to change a bit, however, and the American Marketing Association was the catalyst for the beginnings of some focused inquiry. Conceptual and empirical thrusts then began to appear under such rubrics as risk and diffusion of innovations. The early models of consumer behavior were published, and the field began to receive the shape and direction which continues to this day.

The most meaningful change along the way has been the gradual shift from wholesale borrowing from related behavioral sciences to something much broader. Consumer research has emerged as a legitimate discipline. In the 1960's, few in the parent fields would dirty their hands in our arena. Those active here were all too often typed as the great contaminators of pristine truths as we began to see whether or not the stuff published in lofty journals proved out in real life. But that was to change pretty quickly. My Ohio State colleagues and I noted this most graphically when one of our noted psychologists did a real about face. Rather than the frequent volleys across campus and occasional harassment of courageous graduate students, he began to ask us to cut him in on the action, especially the consulting. I cannot condemn his earlier reactions; to some extent they were entirely deserved. The later response simply

underscored a growing recognition that consumer research was approaching legitimacy. Now it is a valid area of human life for scholarly study, and research from here has percolated its way back into these parent fields in a notable way.

Yes, we have moved beyond infancy. Let me point out some things that I feel are real signs of progress.

A Decline in the "Theory of the Month Club"

This club referred to above received some of its early impetus from me as I dabbled around with the theory of cognitive dissonance. Quite rightly I reasoned that this was a sure way to break into print, and off my career went. Those early publications will not go down in history as permanent landmarks by any means; nor will a majority of the other stuff which followed. Yet, looking back, this was more a sign of an infant discipline than anything else. After all, we had to start somewhere.

Embracing the theory of the month club today, however, is a sad vestigial remain of a bygone era. It is declining, because most of us don't rise up and uncritically salute the latest thing anymore. I am glad, for example, to see the advocates of attribution theory challenged to show what, if anything, it has contributed to existing knowledge.

Gains in Methodological Sophistication

In sharp contrast to earlier times, a large percentage of those who publish today evidence signs of good methodological grounding. While I feel this has led to undue preoccupation with "number crunching," it is a definite sign of maturation. The same can be said of the growing focus on validity.

A Tradition of Replication

Quite a few who read this paper will recoil at the very mention of multi-attribute models. To be sure, some have ridden this horse into the wall. Nevertheless, our preoccupation with this model has reflected a very good thing--the development of a tradition of replication. Because of the evidence that has accumulated over the past decade, we now are able to reflect meaningfully on the contribution this model makes. Frankly, progress can occur in no other way as I have long argued, because nothing firm can be concluded from the results of an isolated study here and there on a given issue. We are now seeing significant replication in such areas as information processing and choice heuristics, and I applaud it.

Some Consensus on Research Priorities

The first meetings of ACR were little more than everyone doing our own thing to get on the program and have our way paid. This also was reflected in the broader literature of the field. We are not far beyond that point today, but there is at least the beginning of some consensus on those areas which most need investigation. This too is an encouraging sign. While this is not the place to state my own priorities (that will appear in the fourth edition of Consumer Behavior), some welcome developments are the recent focuses on the dynamics of information processing,

theories of involvement, satisfaction, and non-product consumer behavior, just to mention a few examples.

The Crossroads: Maturity or Not?

Progress is being made, and let's be grateful for it. It certainly makes the revision of Consumer Behavior a less traumatic experience. The upheaval in the literature between the first couple of editions forced us into some really tough reconceptualization. While the volume of research has not abated recently, the field has settled a good bit into a more definitive pattern. This allows us to focus in the fourth edition on new insights into the old questions and the implications which emerge. This is a liberating experience.

I cannot escape the conclusion, however, that this discipline still is far from maturity. It still is possible to write something roughly categorized as "behavioral" and get it published with precious little inquiry into its methodological validity or substantive contribution. In a sense we are now at a crossroads if we want to maintain progress. It is time to take stock of what we are doing and where we are going. Here are some of the major issues to be faced.

The Criterion of Relevance

In the first years of ACR some of us used to debate the issue of basic versus applied research with some acrimony. Nothing has changed my opinion that this issue is a straw man based on a misconception of the very nature of our field.

Two decades ago, Ithiel de sola Pool described marketing as an engineering discipline drawing heavily upon related sciences and fields of inquiry to bring insight into the solution of practical problems. While consumer research reaches far beyond the boundaries of marketing, in what sense is it anything other than an engineering discipline as well? Is not the ultimate concern to shed light on the dynamics of consumer behavior so that those involved in the practical arena can do a better job? Contrast it with my parent field of social psychology which is not engineering and is a distinct field unto itself. If its professional contributors want to confine their research to such issues as prisoner dilemma games and other concerns pretty far removed from practice, it is perfectly fair game. We do not have that same right, however,

Some will disagree, but I do not think our discipline will go far beyond adolescence until relevance becomes a more central criterion. What I mean is that research priorities must be based on substantive issues reflecting the needs of decision makers. If research does not ultimately have some practical impact, no matter how small, how can we justify it? In this sense, we have a mighty long way to go. To paraphrase a little doggerel attributed I think to Kenneth Boulding:

Research is like a blunderbuss.
For all our muss and fuss,
We fire a monstrous charge of shot,
And sometimes hit but mostly not.

Frankly, there was a time in my own professional career where the sole concern was publication by any means and building a reputation among my academic peers. Then, I began to ask this disturbing question: "Of all the things I have written, what impact has it had on business practice?" My conclusion was that the impact was pretty nearly zero. Should I have cared? After all, most of you active at that time were using my books and giving the usual professional accolades. But I could not escape

de sola Pool's insights, and the whole focus of my life changed.

Increasingly I found myself trying to sort out the issues being faced by practitioners and the ways behavioral research could contribute. Obviously it became clear that this would at times require basic research which, at that point in time, would be pretty far removed from the firing line so to speak. But that focus has remained, and I make a plea that it be the ultimate criterion underlying all we do. I am tired of reading that obligatory section in professional papers entitled "practical implications." The straining we do approaches absurdity. Pragmatic issues should be upfront at the very outset rather than a forced and frequently trivial conclusion. When this criterion is applied rigorously, a large part of our published erudition quickly dissolves into obscurity.

Let me now put the same question to all of us. What concepts and methods have diffused from our research into the various fields of practice? Some will quickly identify psychographics and MDS/conjoint analysis as prime examples. But where did these contributions originate and have their greatest development? I think you will find that the diffusion process was just the reverse--from practice into the academe. So who is leading whom? At times it seems as if the practitioner and the academician live in different worlds.

Perhaps it will help if I describe briefly how the diffusion process has occurred in one area of non-product marketing. This is the field of Christian communication in which I have been actively engaged since coming to Wheaton. Our focus from the outset has been on the needs of decision makers in the local church, publishers, broadcasters, mission boards, and so on. They continue to ask for serious help, and many of the answers can be found in research. The Wheaton group alone has completed over 200 research studies on such bread and butter issues as readership, listenership, felt needs, and so on. By and large, these are methodologically unsophisticated, but they have found their way into practice. In the process we have derived a simple hierarchy of effects type model of spiritual decision making which now is the basis of evangelistic strategy around the world. This diffusion has occurred over a mighty short time period. We have no choice but to be relevant, and the outcome is an absence of dichotomy between academic and practical. Even more revealing is that an academic field of inquiry has arisen in the process. This is how it should be in my opinion.

Isn't it time for us to quit playing games? How many practitioners are at this conference? There are some, but ACR has always had a thin mix in spite of the contrary vision we had at the outset. Whose fault is it that an advertising researcher and I finally gave up on the sessions at a recent ACR meeting and decided we would benefit much more by informal conversation with those we could find who were doing some relevant things.

This perhaps is a lengthy and wordy way of saying something very simple. It is time to go beyond mere number crunching and insist that researchers have a firm and clear answer to the question, "so what?" If this is not our central focus, we are destined to permanent adolescence.

Moving Beyond Ethocentrism

This issue will require fewer words, but it is a serious challenge for all of us. I am appalled at the western domination in the consumer literature. Here and there is it possible to find a cross-cultural application, but these almost invariably reflect a profound western bias. Must we cast the rest of the world into our mold? Naive application of western models and methods can lead to decidedly erroneous conclusions and set back the hopes

and dreams of non-western leaders seeking solutions in their unique environment.

Serious cross cultural consumer research is a must in a world characterized by rising materialistic aspirations and imbalanced distribution of resources. Such research must be grounded in cultural anthropology, however, if we are to take account of profound behavioral variation. I have learned this lesson the hard way through working in research and training in more than 50 countries since 1972. Here is a vast frontier where we can join hands meaningfully with properly trained research partners throughout the world. In this context, the training of researchers in non-western countries is an absolute necessity. I see this need unmet wherever I go, and I often wonder why so many of you who first came to the United States as students remain here when there are such desperate needs at home. You above all have an obligation to meet these international responsibilities.

A Recognition of Moral Issues

I cannot imagine a discipline which is more amoral than ours. Only rarely do we address the social implications of what we are doing. What are the longrun implications, for example, of our continued focus on a high and rising standard of living in a era of diminishing natural resources? Is our growing knowledge of the mechanics of information processing gradually giving us the means of persuasion against a person's will? These are just two examples of issues which must come to the forefront rather than being relegated to the sidelines.

Moving From Adolescence to Maturity

I have presented a mixed picture so far--encouragement on the one hand and serious concerns on the other. Hopefully, the concerns expressed have struck a responsive note with some, and it is these colleagues to which these closing comments are addressed.

The starting point in the move from adolescence to maturity is for all serious contributors in this field to rethink their own conception of professional success. As I mentioned earlier, much of my own career was based on success as defined by publication in a "refereed" journal and recognition by peers. Relevance of what I had to say was secondary. Success, in short, is to be found in the length and nature of a publication list.

I have only given part of the picture on the changes which occurred in my life years ago, and I would be remiss by not filling in the remainder. I also had to face the deeper question of whether or not recognition and achievement really is a sufficient foundation for life itself, because it became increasingly non-satisfying. Fortunately my wife and I began a great adventure 15 years ago as we began for the first time to take our Christian faith seriously and place this eternal dimension at the center of our lives. That adventure continues to this day. It has led to a profound change in personal motivation as I have been freed to focus on basic issues from a perspective of some well-formed and functioning values which have their roots beyond myself.

While my own story is unique to me in many ways, I have found that many in this field are walking to the same dummer I have described here. The tragedy is that the reward system within our institutions and within this field itself only encourages it. I would again plead for the establishment of practical relevance as the guiding focus in all that we do. This would mean, of course, that our reward system must take account of the extent to which our research makes a genuine contribution in the context

of a substantive issue that ultimately will have some influence on practice.

Since this type of criterion is not likely to replace the narrowly focused publish or perish criterion used in our academic institutions, ACR will have to take the lead. We must become a true forum of researchers and decision makers, of academicians and practitioners. We have reached the point of sufficient maturity that we can begin to come to some real closure on research priorities. These priorities, in turn, must be enforced rigorously by those who serve as research reviewers and referees.

These priorities also must be based in serious reflection on the moral and social dilemmas which confront us. Yes, this is an area which goes beyond numbers into values, but we must not lose sight of the fact that we are dealing with human beings and not just rats in laboratories.

Can we rise to these challenges? Only time will tell, but I will do my best to be a part of the solution. While I am not so visible in "mainline" circles as I once was, this is only because of the arena in which I work. I hope to remain as a functioning and responsible contributor to this field for years to come.

WHAT IS LOW INVOLVEMENT LOW IN?

Clark Leavitt, The Ohio State University¹
Anthony G. Greenwald, The Ohio State University
Carl Obermiller, The Ohio State University

Abstract

Consumer psychologists have disagreed in their theories about what constitutes high involvement, necessarily leaving the important phenomenon of low involvement ambiguous. After reviewing the relevant consumer and cognitive psychology concepts, we offer a 3-stage information processing model in which high involvement is associated with the third stage--elaborated encoding of (that is, extensive cognitive responding to) advertising messages. Our model associates different types of low involvement with each of its first two stages--preattentive processing and focal attention. Both of these types of low involvement--inattentive and attentive--can lead to advertising impact.

* * * * *

One of us (Leavitt and Walton 1978) has suggested elsewhere that the paradigm that has been applied to persuasive communication is an adversary model of interaction which pictures persuasion as a kind of contest. The persuader's role is to move the audience to action by rhetoric; by promise of reward, or any other means. The target--the audience member--resists, is critical, and uses reasoning and skepticism to emphasize the flaws in the appeals.

An alternative to the adversary paradigm is unclear. Perhaps it is a kind of informal learning in which the self plays an instrumental role rather than acting as a goal. In any case, the adversary model is congenial to the notion of ego involvement which is a topic of some interest recently to one of us (Greenwald, in press). We began this paper with the notion that the adversary paradigm and its embodiment in ego involvement in particular, would provide a key to understanding the concept of involvement in consumer psychology. Consumer psychologists have been interested particularly in low involvement, and ego involvement is high involvement. By using little more than reverse English, we thought, we should arrive at the meaning of low involvement.

Perhaps fortunately, the conceptual analysis of consumer involvement turned out to provide a more complex challenge than we anticipated. We shall retrace our path by looking first at prominent attempts to define involvement in consumer research, next reviewing the relevant theoretical concepts in social and cognitive psychology, and lastly presenting our conclusions about the nature of consumer involvement.

1. The Involvement Concept in Consumer Research

Krugman

Most of the paths followed by consumer psychologists in their recent investigations of involvement emanate from an article that appeared in Public Opinion Quarterly in 1965, by Herbert Krugman. Because of the importance of that article to subsequent treatments of involvement, it is worth indulging in a complete quotation of the definition of involvement Krugman offered at that time:

¹Draft of August 11, 1980. Address reprint requests to Clark Leavitt, The Ohio State University, 1775 College Road, Columbus, Ohio 43210.

(There are) two entirely different ways of experiencing and being influenced by mass media. One way is characterized by lack of personal involvement, which, while perhaps more common in response to commercial subject matter, is by no means limited to it. The second is characterized by a high degree of personal involvement. By this we do not mean attention, interest, or excitement but the number of conscious "bridging experiences," connections, or personal references per minute that the viewer makes between his own life and the stimulus. This may vary from none to many.

The significance of conditions of low or high involvement is not that one is better than the other, but that the processes of communication impact are different. That is, there is a difference in the change processes that are at work. Thus, with low involvement one might look for gradual shifts in perceptual structure, aided by repetition, activated by behavioral-choice situations, and followed at some time by attitude change. With high involvement one would look for the classic, more dramatic, and more familiar conflict of ideas at the level of conscious opinion and attitude that precedes changes in overt behavior.

For our purposes, the most significant aspects of Krugman's analysis were (a) his specific disavowal of the interpretation that involvement might mean level of attention, interest, or excitement, (b) his reference to lack of personal connections in the case of low involvement, and (c) his suggestion that information processing followed a different route when involvement was low rather than high. In an article appearing two years later, Krugman (1967) added the important proposal that television was a medium that characteristically elicited low involvement, while print elicited high involvement.²

Ray et al.

In a 1973 article, Michael Ray along with several others incorporated a modification of Krugman's low-involvement processing concept into a broader analysis of variations in the sequence of changes in affect, behavior, and cognition that might occur following receipt of a communication. Krugman's high-involvement processing corresponds to Ray et al.'s learning hierarchy. It is not immediately clear whether Ray et al.'s low involvement hierarchy or their dissonance-attribution hierarchy should be taken as more nearly equivalent of Krugman's low-involvement processing. In a recent discussion of just this point, Calder (1979) suggested that low involvement might be best conceived in terms of a direct impact of communication on behavior

²In a 1971 article, Krugman added the speculation that brain wave patterns might be used to assess low vs. high involvement, but it may be best to regard that suggestion as a digression, since it seems to lead the concept of involvement away from his disavowal of an interpretation in terms of attention and excitement.

rather than an impact that is mediated by cognitive change.³

Houston & Rothschild

Houston and Rothschild (1977) have distinguished three types of involvement in the context of their decision-making analysis of consumer behavior. Their concept of involvement corresponds approximately to personal importance, which is a common feature with Krugman's analysis. The significance of their contribution is in recognizing that importance or involvement may be a consequence not only of the circumstances in which a message is received (they refer to this as situational involvement), but also of unique characteristics of the recipient (which they identify as enduring involvement). Their third type of involvement, response involvement, is defined as "the complexity or extensiveness of cognitive and behavioral processes characterizing the overall consumer decision process." (p. 5). Also, they conceive response involvement as reflecting the combined influence of situational and enduring involvement. Thus, the first two types of involvement represent sources of involvement (in the situation and person, respectively) while the third type captures the role of involvement in causing detailed cognitive processing. The association of involvement with an elaborated form of cognitive processing is an assumption shared with both Krugman and Ray et al., but the decision-making framework of the Houston and Rothschild analysis of cognitive processing is quite different from the cognitive models used by Krugman and Ray et al.

Mitchell

Houston and Rothschild's analysis of involvement in terms of a detailed set of cognitive processes provides a contrasting background for Andrew Mitchell's (1979) proposal that involvement be defined as a state, rather than a process (p. 194). Mitchell starts from a conception of involvement as meaning relevance to an important or high priority personal goal--a concept that fits well enough with the meaning of personal importance that underlies the other conceptions we have reviewed. Mitchell, however, proceeds in a different direction when he defines involvement as indicating "the amount of arousal, interest, or drive evoked by a particular stimulus or situation" (1979, p. 194). It is appropriate to recall Krugman's exclusion of "attention, interest, or excitement" from his (1965) conception of high involvement.

In summary, although there has been consensus that high involvement means personal importance, consumer behavior theorists have shown little agreement regarding the psychological analysis of importance--alternatively interpreting it in terms of personal connections, sequence of information processing, complexity of processing, and degree of arousal. This uncertainty about high involvement necessarily leaves the theoretical analysis of low involvement unsettled. We turn for help to several involvement-related concepts from social and cognitive psychology.

2. Involvement-Related Concepts in Psychology

First we consider three psychological approaches to the nature of information processing associated with high involvement--cognitive response analysis, encoding elaboration theory, and ego task analysis.

³Krugman's original (1965) statement, "with low involvement one might look for gradual shifts in perceptual structure, aided by repetition, activated by behavioral-choice situations, and followed at some time by attitude change," (p.) is ambiguous. Its interpretation in terms of the Ray et al. hierarchies depends on whether we care to interpret "gradual perceptual shifts" as a full-fledged cognitive stage or not.

Cognitive response analysis (Greenwald 1968; Petty, Ostrom & Brock 1980) holds that the cognitive reactions of the recipient of a persuasive communication are more important than is the actual communication content in determining the impact of a persuasive message. The effect of a message thus depends on whether the recipient's cognitive responses support or oppose the message's conclusion. Petty and Cacioppo (1979) recently showed that an involvement manipulation resulted in increased cognitive response activity--a finding that provides a nice link between Krugman's analysis of involvement in terms of personal connections and the cognitive response theory.

However, personal connections or bridging experiences are not the only kinds of cognitive responses that may occur in response to a persuasive message. Recent cognitive psychological theory about the role of degree of elaboration in encoding of information provides further connections among the concept of consumer involvement, cognitive response theory, and a variety of memory phenomena.⁴ The more elaborate, or detailed, is the encoding of an item of information (i.e., the more different ways it is categorized), the more likely it is to be recalled later. Some recent work by T. B. Rogers and his colleagues (Rogers et al. 1977; Kuiper & Rogers 1979) has shown that the task of judging the relevance of trait words to oneself has the properties of elaborated encoding, producing even better memory for the trait words than do other tasks thought to involve high degrees of elaboration (such as making a judgment about the meaning of the trait). In other words, relating information to the self entails substantial elaboration. Extending this theory to the advertising communication domain, we have a strong basis for predicting that the greater the self relevance of the topic of a message, the more elaborate the processing of the content and therefore the better the memory for the message.

The cognitive response and encoding elaboration theories offer useful accounts of effects of involvement on cognitive responses to, and memory for, an advertising message. Important questions still needing answers are: (a) How do people vary in what they find important? and (b) Do such variations between people have significance for the processing or impact of advertising communications? Greenwald's (in press) recent review of the ego-involvement concept in social psychology led to an approach called ego task analysis, which provides a basis for addressing these questions. An ego task is a long-persisting task, which means that it is directed to a distant--perhaps unattainable--goal, and subsumes tasks that are directed at immediately available goals--goals that may be only temporarily important.

Two ego tasks that seem pervasive in daily social existence are impression management (achieving a satisfactory image in the eyes of others) and self-image management (achieving a satisfactory self-evaluation). The analysis of ego tasks can be applied to consumer involvement by considering the relation of advertising content to the various short-term and long-term tasks of the consumer, and to the impression and self-image management tasks in particular. It is interesting to observe that, although most heavily advertised products are instrumental in achieving some immediate and concrete goals, advertisers often choose to appeal to the more generalized goals of ego tasks. Thus, cigarettes are advertised not in terms of their effects on level of arousal or on reduction of social tension, but in terms of the image of the person who uses the advertised brand.

⁴The encoding elaboration view previously was identified as a theory of levels of processing (Craik & Lockhart 1972), but the "levels" metaphor has seemed inappropriate on the basis of more recent findings (e.g., Craik & Tulving 1975).

Automobiles are advertised partly in terms of their transportation virtues, but even more in terms of the image of the person who drives the advertised model. Advertisers are imaginative in manufacturing connections of products to ego tasks--one of our favorites is the dishwasher detergent advertised by showing a housewife whose clean, shiny dishes cast "a nice reflection" on her. To the extent that the audience member shares such ego-task goals of the advertisement's protagonist--who achieves a favorable self-image or a favorable impression by using the recommended brand--the ad helps the involvement process; that is, it helps to establish personal connections to the brand. Further, to the extent that various audience segments are characterized by different ego tasks, the same type of appeal will not work best for all. Thus, it is not surprising that some cigarette brands appeal to health by advertising low tar and filters, while others appeal to an image of social or sexual success.

Ego tasks are not the only form of activity that might give us some clues about the nature of involvement. Ego-involvement is a subset of task-involvement, the highest level of that broader category. Lower level task involvement may also be intrinsically motivating and may elicit elaborated processing of advertising messages. Unlike ego involvement, task involvement occurs where there is intrinsic motivation but no special self-relevance (de Charms 1968). In fact, Csikszentmihalyi (1975) found that his more task-involved subjects were less self-conscious.

Although the cognitive response, encoding elaboration, and ego task analyses provide a coherent conception of high consumer involvement, they still only characterize low involvement indirectly. (This is where our reverse English fails!) To get psychologically closer to low involvement we consider a few concepts that have become familiar in research on learning and on selective attention.

As a characterization of low-involvement processes, the study of animal learning gives us the concept of latent learning (learning in the absence of relevant motivation), and research on human verbal learning gives us the somewhat related concept of incidental learning (learning without intention to learn). These principles lead us to expect that learning will occur under low-involvement conditions, but it may be weaker learning than when motivation or intention are present.

Cognitive psychology has provided us with the contrast between focal attention and preattentive processing. Information is assumed to be processed via a limited-capacity channel when it achieves focal attention, and this channel (sometimes called short-term memory, active memory, or primary memory) is assumed to be the entry route to long-term memory. Information that is outside of focal attention is expected to receive some immediate processing, but to leave no long-term memory residue. This contrast is suggestive, but the problem arises--where to locate low-involvement processing. Is it characterized by focal attention or does it occur instead outside of focal attention?

Figure 1 provides a basis for interrelating the several psychological principles that have been discussed in this section. The basic scheme of the figure employs the sequential-stages conception of information processing, which has been the dominant paradigm of cognitive psychology in recent years. (Although we find this paradigm heuristically useful, we will question one aspect of it in the third part of this paper). In Figure 1, the interpretations of high involvement as cognitive responding or as establishing personal connections are grouped together as variations on the theme of encoding elaboration. With high involvement, the elaboration provided by the audience member should vary from person to person; ego task analysis can be used as one way to analyze these individual differences. People who are highly involved may

nonetheless be engaged in very different tasks.

Figure 1 reveals our dilemma in the conceptual location of low involvement. If it is identified with failure of the message to reach a stage of focal attention, then we should expect no memory for the message, and presumably no impact. Since the major analyses of low consumer involvement lead us to expect impact, we are inclined to identify low involvement instead with achievement of focal attention, accompanied by minimal encoding. These two options are identified by different subscripts in Figure 1. It is low involvement₂ that corresponds to the principles of latent and incidental learning in the experimental psychology literature.

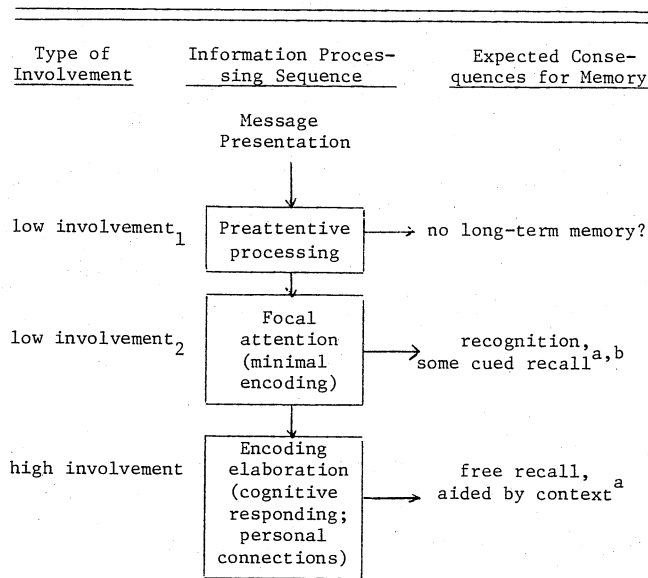

3. The Effectiveness of Low Involvement

Two Types of Low Involvement

Our consideration of a form of low consumer involvement that operates outside of focal attention is encouraged by Zajonc's (1980) recent criticism of the prevailing view that affective judgments are cognitively mediated--that is, his criticism of the view that we use our beliefs or cognitions about an object as the basis for evaluating the object. Zajonc's critique rested partly on the empirical observation that affective reactions often occur too rapidly to be cognitively mediated. If, as Zajonc suggests, affect and cognition are independent systems, then affective reactions could be influenced by information that impinges on the nervous system but does not penetrate the cognitive system of focal attention.

FIGURE 1

Message Processing, Involvement, and Memory

^aThe principle of encoding specificity (Tulving & Thomson 1973) is used to predict that recall will be aided by the cues or categories used in original encoding. To the extent that these cues can be supplied by the audience member unaided, "free" recall should be likely.

^bWith minimal encoding, situational cues present during original exposure to the message may effectively elicit recall.

A reformulation of Figure 1 that incorporates this possibility is given in Figure 2, which describes a segment of a multisystem analysis of human information processing (Greenwald in press b). In Figure 2, the system of focal attention and long-term memory (that is, the cognitive system) is not the only route by which input information can influence behavior. A second (noncognitive) path is proposed. In addition to Zajonc's evidence for affective-cognitive independence, some other support for the existence of the noncognitive path comes from several staple phenomena of contemporary social psychology: (a) discrepancies between verbal and nonverbal communications that emanate from the same person (Ekman & Friesan 1969), (b) inconsistencies between stated attitude and overt behavior (Wicker 1969), and (c) the pervasive occurrence of influences on human behavior that cannot be reported accurately by the cognitive system (Nisbett & Wilson, 1977).

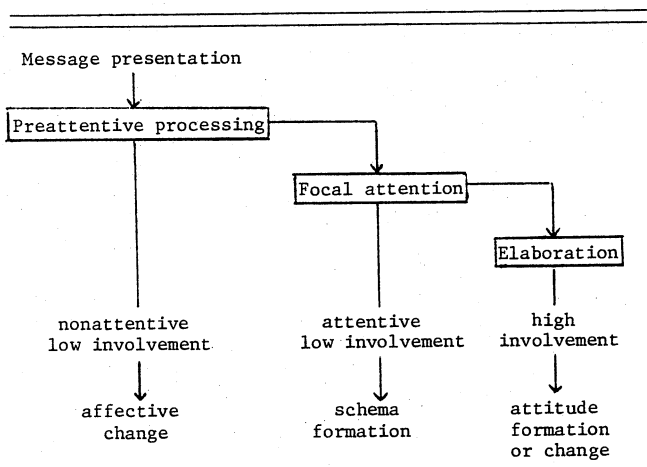

We shall refer to the two types of low involvement shown in Figure 2 as nonattentive and attentive low involvement. In proposing the nonattentive variety of low involvement, we do mean to suggest that an unattended advertising message may influence behavior without the audience member having any verbally reportable knowledge of this influence.

Three Bases for Effectiveness of Low Involvement

In most cases, high-involving advertising messages should be more effective than low-involving ones because the former should be better remembered. Nonetheless, there are at least three bases for expecting that low-involving messages can be effective with repeated exposures. In discussing the effects of low involvement we shall assume that information can be processed simultaneously by the cognitive and noncognitive paths shown in Figure 2.

FIGURE 2

Varieties of Involvement

Note: As processing proceeds from preattentive processing to focal attention and to encoding elaboration, the later processes should add to (rather than replace) the earlier ones. However, since the later processes may also be likely to have more powerful consequences for behavior, their effects may predominate. The effect of the high-involvement path is referred to as formation or change of an attitude because it represents an integrated effect on affect and cognition.

1. Reduced counterarguing. First we consider a circumstance under which low involvement may enhance the

effectiveness of a focally attended message. If the cognitive response elicited by a message would tend to oppose its effect--as in the case of a political advertisement for a candidate one intends to vote against--then the audience's lack of elaborative encoding may be more desirable than the presence of such elaboration from the advertiser's perspective.

2. Learning by repetition. Certain effects do not require elaborative encoding, and can therefore occur quite successfully with low involvement. In particular the aim of establishing a simple schema in the audience's memory can be achieved by means of repetition when there is only minimal encoding. You don't have to have been highly involved with the relevant ads to find yourself tending to respond to a bartender's "What'll you have?" by thinking (if not saying) "Pabst Blue Ribbon." The low-involving repetition of this message, with the accompaniment of a musical theme that aids in organizing the response together with the question, unavoidably establishes the desired scheme in listeners who are exposed to it often enough. One of us (Leavitt 1961) has previously analyzed the role of stimulus qualities of advertising messages in facilitating recall that may be dependent only on minimal encoding. The attention-holding characteristic that Leavitt designated intrigue may be all that is needed to produce this sort of learning.⁵

3. Learning without attention. Zajonc (1980), in his paper on the separateness of cognitive and affective systems, reported several studies in which repeated exposure to a stimulus increased the liking for that stimulus without apparent cognitive mediation. In one of these studies (Wilson 1979) the repeated stimuli were presented in the unattended ear in a dichotic listening task, to assure that their effect was not mediated by focal attention. It is such results that prompt us not to dismiss the importance to consumer psychology of the nonattentive variety of low involvement.

Conclusion

The first two of our suggested mechanisms of low-involvement persuasion--reduction of counterarguing and learning via repetition--fit well with existing theory in social and cognitive psychology. The third--learning without attention--does not. Nonetheless, and even though we count ourselves among those who look skeptically at claims of "hidden persuasion" and "subliminal influence," we believe that the proposal of noncognitively mediated influence should receive serious consideration. Needless to say, it will be a challenge to researchers to develop designs and procedures that can convincingly demonstrate influences on consumer behavior that occur without self-conscious cognitive mediation.

⁵This perceptual learning perhaps resembles the process by which very young children develop object schemas--before they have much of a cognitive structure that is capable of providing elaborative encoding. This similarity to perceptual learning may allow insight into a phenomenon that must have been noticed by every parent who has ever observed a child in front of a television set--a degree of rapt attention to advertisements that often exceeds attention to other programming. Although this attention may be very focused, it may often not meet our conceptual criterion of high involvement because there may be only minimal elaborative encoding (or cognitive responding). The resulting schema may be easily recognized or elicited by appropriate cues (as when the child accompanies the parent to market), even though it is not readily producible in free recall.

ISSUE INVOLVEMENT AS A MODERATOR OF THE EFFECTS ON ATTITUDE
OF ADVERTISING CONTENT AND CONTEXT

Richard E. Petty, University of Missouri-Columbia
John T. Cacioppo, University of Iowa

Abstract

Two persuasion experiments were conducted manipulating the personal relevance of the message, the quality of the arguments employed, and the characteristics of the message source. The results suggested that message content factors are more influential than source characteristics under high involvement conditions. The reverse tends to occur under low involvement.

The Involvement Concept

Persuasion researchers within both social and consumer psychology have recently emphasized the need to distinguish between high and low involvement situations (cf., Petty, Cacioppo, & Heesacker 1981, Ray 1976). Although there are many specific definitions of "involvement" within both disciplines, there is considerable agreement that in high involvement situations, the persuasive message under consideration has a high degree of personal relevance to the recipient, whereas in low involvement situations, the personal relevance of the message is rather trivial. In social psychology, this view is best represented by the work of the Sherifs who have argued that high involvement occurs when the message has "intrinsic importance" (Sherif & Hovland 1961, p. 197) or "personal meaning" (Sherif et al. 1973, p. 311), and in consumer psychology this view is well-represented by Krugman (1965) who defines involvement as the number of "personal references" or connections that recipients make between the message and their own lives (p. 355).

Despite the widespread agreement that involvement has something to do with the personal relevance of a message, there is little agreement on the research operations employed in studying involvement. Some of the research on involvement conducted by both social (e.g., Hovland, Harvey, & Sherif 1957) and consumer (e.g., Newman & Dolich 1979) psychologists has investigated existing groups that differed in the extent to which an issue or product was personally important, or has employed designs allowing subjects to assign themselves to high and low involvement groups. These methods, which are correlational in nature, confound involvement with all other existing differences between the high and low involvement groups. Other social (e.g., Rhine & Severance 1970) and consumer psychologists (e.g., Lastovicka & Gardner 1979) have defined involvement in terms of the specific issue or product under consideration. This procedure, of course, confounds involvement with aspects of the issue or product that are immaterial to their personal relevance. Finally, some researchers have studied involvement by varying the medium of message presentation. Interestingly, however, some investigators have argued that television is a more involving medium than is print (Worchel et al. 1975), whereas others have argued just the opposite (Krugman 1967). A preferable procedure that keeps recipient, message, and medium characteristics constant for high and low involvement conditions was introduced by Apsler & Sears (1968) and is the method employed in the studies to be reported here. In this procedure subjects are randomly assigned to high and low involvement conditions and receive the same message via the same medium, but high involvement subjects are led to believe that the issue or product has some personal relevance whereas low involvement subjects are not.

In addition to the methodological differences that have plagued the involvement concept, another area of disagreement concerns the effects on persuasion that involvement is expected to have. The Sherifs have argued that increased involvement is associated with increased resistance to persuasion (cf., Sherif, Sherif, & Nebergall 1965). The notion is that on any given issue, highly involved persons exhibit more negative evaluations of a communication because high involvement is associated with an extended "latitude of rejection." Thus, incoming messages on high involvement issues are thought to have an enhanced probability of being rejected because they are more likely to fall within the unacceptable range of a person's implicit attitude continuum. This view has received considerable acceptance within social psychology (e.g., Eagly & Manis 1966, Greenwald 1980). Krugman (1965) has proposed an alternative view that has achieved considerable acceptance within consumer psychology (e.g., Ray 1974, Rothchild 1979). Under this second view, increasing involvement does not invariably increase resistance to persuasion, but instead shifts the sequence of communication impact. Krugman argues that under high involvement, a communication affects cognitions, then attitudes, then behavior, whereas under low involvement a communication affects cognitions, then behavior, and then attitudes. The focal goal of the present paper is to present and test a third view of how involvement affects persuasion.

Involvement as a Determinant of
Content-based Persuasion

Elsewhere we have proposed that the level of involvement directs the focus of a subject's thoughts about a persuasive communication (Petty & Cacioppo 1979). Specifically, we have suggested that under high involvement conditions, the focus of thought is on the content of the persuasive message, whereas under low involvement conditions, the focus of thought is on non-content cues. Thus, under high involvement, if the communication presents arguments that are subjectively cogent and compelling, the recipient's thoughts will be primarily favorable and persuasion will result. If the communication presents arguments that are subjectively specious and subject to counterargumentation, resistance to persuasion (and perhaps boomerang) will occur. Thus, contrary to the Sherifs' view, increasing involvement can lead to either enhanced or reduced persuasion depending upon the quality of the arguments presented in the message.

In contrast to this focus on the content of a message under high involvement conditions, we have suggested that subjects who are not involved are more likely to focus on such non-content cues as the rewards available for adopting a certain attitude, the attractiveness, credibility, or power of the communication's source, and the number of others who advocate a certain position. Focusing on each of the latter aspects of a communication allows a person to evaluate a message or decide what attitudinal position to adopt without engaging in any extensive cognitive work relevant to the issue or product under consideration. As Miller et al. (1976) noted: "It may be irrational to scrutinize the plethora of counter-attitudinal messages received daily. To the extent that one possesses only a limited amount of information processing time and capacity, such scrutiny would disengage the thought processes from the exigencies of daily life" (p. 623). Thus, when a

person is not highly involved with a persuasive message (i.e., when the message has no personal consequences), we propose that the person relies on a short-cut means of evaluation. Although, like Krugman, we are proposing that there are separate processes governing persuasion under high and low involvement, unlike Krugman we believe that the sequence of communication impact is the same--cognitions, attitudes, then behaviors. The difference between the two processes lies in what cognitions are affected--cognitions dealing with issue-relevant argumentation (high involvement), or cognitions dealing with non-content features of the influence situation (low involvement).

Empirical Tests of the Involvement Concept

In an initial test of our two-process model of involvement (Petty & Cacioppo 1979), subjects heard a counterattitudinal message containing either strong or weak arguments under conditions of either high or low involvement. As expected, increasing involvement enhanced the production of counterarguments to the weak arguments and increased the production of favorable thoughts to the strong arguments. Consistent with this finding, increasing involvement increased the persuasiveness of the strong arguments, but decreased the persuasiveness of the weak arguments. Although the results of this initial study did support the view that subjects do more thinking about the content of a message under high involvement than under low, it did not directly address whether subjects are more attentive to content-irrelevant cues under low involvement than under high.

Next, we report two experiments designed to test the full two-process model of involvement. In each study, subjects were exposed to a persuasive communication. In Experiment 1 (conducted in collaboration with Rachel Goldman) the message was presented on audio tape and concerned a change in a campus regulation. In Experiment 2, the message was presented in print form and concerned a new consumer product. The following variables were manipulated in each study: (a) the personal relevance of the message (high and low involvement), (b) the quality of the arguments which subjects heard or read in support of the advocated conclusion (strong or weak arguments), and (c) a characteristic of the source presenting the message (high or low expert source in Experiment 1, high or low attractive source in Experiment 2). The two-process model of involvement would expect that under high involvement conditions, persuasion would be affected most by the quality of the message arguments employed, but that under low involvement conditions, persuasion would be tied most strongly to the credibility or attractiveness of the message source.

Experiment 1

One hundred forty-five male and female undergraduates at the University of Missouri participated in order to earn extra credit in an introductory psychology course. The design was a 2 (Issue involvement: high or low) \times 2 (Argument quality: strong or weak) \times 2 (Source credibility: high or low) factorial. Subjects were run in groups of 3 to 16 in cubicles designed so that no subject could have visual or verbal contact with any other subject. Upon arrival at the laboratory, subjects read that they would be rating tapes for their sound quality. After reading these instructions, subjects heard one of four tapes over headphones. After listening to the appropriate communication, subjects completed the dependent variable booklets, and were then debriefed, thanked, and dismissed.

Independent Variables

Argument quality. All subjects heard a communication that advocated that seniors be required to pass a comprehensive exam in their major area as a requirement for graduation. The strong version of the message provided persuasive evidence (statistics, data, etc.) in support of the

exam (e.g. institution of the exams has led to a reversal in the declining scores on standardized achievement tests at other universities). In contrast, the weak version of the message relied more on quotations and personal opinion and examples to support its position (e.g. the author's major advisor took a comprehensive exam and now had a prestigious academic position). The strong arguments were taken from a pool that had elicited primarily favorable thoughts in a pretest, and the weak arguments were taken from a pool that had elicited primarily counterarguments.

Issue involvement. Subjects in the high involvement conditions heard the speaker advocate that the comprehensive exams should begin in the 1979-1980 academic year at their university (in which case they would all be affected personally by the proposal). In the low involvement conditions, the speaker advocated that the exams be initiated in the 1989-1990 academic term.

Source credibility. The high credible source was described as a professor of education from Princeton University who had conducted a study of comprehensive exams nationally. The low credible source was a junior at a local high school who had prepared a term paper on the topic.

Dependent Variables

After hearing the tape, subjects completed two measures of opinion about the topic. First, subjects rated the concept "senior comprehensive exams" on four 9-point semantic differential scales (harmful-beneficial, wise-foolish, good-bad, favorable-unfavorable) that were summed to form a general measure of evaluation. Next, subjects responded to an 11-point Likert-type scale concerning their extent of agreement with the speaker's proposal. The responses to these two attitude measures were converted to standard scores and averaged to form an index of communication acceptance.

Following the key attitude measures, subjects completed some manipulation check measures and other ancillary questions. Finally they were given 4 minutes to list as many of the arguments provided in the communication as they could remember. Two judges, blind to the experimental conditions rated each argument listed for accuracy ($r = .92$). Similar statements of the same argument were only counted once. Disagreements between judges were resolved by consulting a third judge.

Results

Analyses on the manipulation check measures indicated that the three independent variables were successfully varied. Subjects hearing the high credibility speaker rated him as more "qualified" ($M = 6.4$) than subjects who were exposed to the low credibility induction ($M = 5.8$), $F(1,137) = 4.86$, $p < .03$. Also, subjects hearing the strong arguments rated their quality as being significantly higher ($M = 8.9$) than subjects exposed to the weak arguments ($M = 4.5$), $F(1,137) = 51.02$, $p < .001$. Finally, subjects in the high involvement condition rated the likelihood that the University of Missouri would institute comprehensive exams during their stay as higher ($M = 5.5$) than subjects in the low involvement conditions ($M = 2.7$), $F(1,137) = 5.12$, $p < .02$.

The means for each cell on the measure of communication acceptance are presented in Table 1, A 2 \times 2 \times 2 analysis of variance on this measure yielded two main effects and two qualifying interactions. A main effect for credibility, $F(1,137) = 6.06$, $p < .02$, indicated that the high credibility communicator induced more acceptance ($M = .21$) than the low credibility communicator ($M = -.21$). A main effect for argument quality revealed that the strong arguments produced more agreement with the position advocated ($M = .36$) than did the weak arguments ($M = -.36$), $F(1,137) = 20.35$, $p < .001$.

Of most interest are the two interactions, however. An Involvement X Arguments interaction, $F(1,137) = 6.05, p < .02$, demonstrated that the strong arguments produced significantly more persuasion than the weak only under conditions of high personal involvement. Also, an Involvement X Credibility interaction, $F(1,137) = 3.92, p < .05$, revealed that the high credibility speaker produced significantly more persuasion than the low only under conditions of low personal involvement.

TABLE 1

EFFECT OF INVOLVEMENT, ARGUMENT QUALITY, AND SOURCE CREDIBILITY ON ATTITUDES TOWARD COMPREHENSIVE EXAMS

	High Involvement		Low Involvement	
	high cred.	low cred.	high cred.	low cred.
Strong Arguments	.62 _{bd}	.58 _{bd}	.38 _{bc}	-.14 _{acd}
Weak Arguments	-.40 _{ac}	-.61 _a	.24 _{bc}	-.65 _a

Note.--Means without a common subscript are significantly different at the .05 level by the Newman-Keuls procedure.

Finally, an analysis of the argument recall scores indicated that subjects were able to recall more of the strong ($M = 4.2$) than the weak ($M = 3.2$) arguments, $F(1,137) = 14.93, p < .001$, but involvement did not affect argument recall.

Discussion

The present study provided evidence for the view that the level of issue involvement is one determinant of whether content or noncontent factors dominate in producing persuasion. When the issue was of high personal relevance to the subjects, the manipulation of argument quality had a significant impact on attitudes, whereas the effect of source credibility was small and not significant. Under low involvement conditions, however, the reverse occurred--source credibility had a large effect on persuasion, but argument quality had little impact. This pattern of results provides strong support for the view that high issue relevance motivates diligent processing of the content of a message. When the issue is relatively uninvolved, however, subjects appear to be unwilling to engage in the effortful cognitive work necessary to evaluate the quality of the arguments.

Under low involvement conditions, subjects were content to form their attitudes on the basis of who said it, rather than on the merits of what was said. In the second experiment, a conceptual replication of Experiment 1 was conducted employing advertising stimuli.

Experiment 2

Two hundred and forty undergraduates at the University of Missouri participated in a study entitled "Evaluations of Advertisements," and received extra credit in an introductory psychology course. The design of the study was a 2 (Product involvement: high or low) X 2 (Message content quality: strong or weak) X 2 (Source attractiveness: high or low) X 2 (Sex of subject). Fifteen subjects were run in each cell of the design in groups of 4 to 8.

Upon arrival at the laboratory, the subjects were told that they would be examining a variety of advertisements and providing their impressions of them. Each subject was handed a booklet containing six magazine ads. Five of the ads were for real but relatively unfamiliar products (e.g. Lux cigarettes, Rolex watches), and one of the ads was for

a fictitious product (Vilance shampoo). The fictitious ad was fifth in the booklet of six and was prepared specifically for the present experiment. The subjects were told to turn through the booklet at their own pace and give a signal to the experimenter when they had finished examining the ads. Following perusal of the ad booklet, subjects completed a dependent variable booklet, and were then debriefed, thanked, and dismissed.

Independent Variables

Product involvement. Preceding each ad in the booklet was a brief description of the purpose of the ad. All subjects read the same descriptions for the real ads, but the description for the bogus Vilance shampoo ad differed for subjects in the high and low involvement conditions. Subjects in the low involvement conditions read:

The product you are about to see is being put out by the Europa Collection based in Vienna, Austria. Their main interest lies in introducing the product to the rest of Europe. Before launching a new European campaign, they have distributed their advertising materials to Journalism schools in the U.S. This is in order to determine if the ad has enough basic appeal to make it worth pursuing. The psychology department is assisting the journalism school in this evaluation.

Subjects in the high involvement conditions read a similar description except that they were told that the company was interested in introducing the product to the United States.

The University of Missouri has been chosen for research purposes. It is for this reason that the product will soon be introduced in the Columbia area. Since you will soon be able to purchase this product in Columbia, the company is asking University students to evaluate their proposed advertisement.

Source attractiveness. Four different advertisements for Vilance shampoo were created to vary the source and message variables. Each ad looked similar in that it presented a male and female in their early 20s giving the reasons why they liked Vilance shampoo. In the high attractive ads a photograph of a couple that previously had been rated as "extremely attractive" was used, and in the low attractive ads a photograph of a couple that previously had been rated as "somewhat unattractive" was used. An "extremely unattractive" stimulus was not used because it did not prove plausible in pilot testing.

Message quality. In the strong argument conditions, the text that accompanied the photograph presented arguments for the shampoo that previously had been rated as compelling and persuasive (e.g. Vilance contains minerals that strengthen each hair shaft so it helps prevent split-ends). In the weak argument conditions, the text presented arguments that previously had been rated as unpersuasive (e.g. Vilance has a down-to-earth brown color that makes us feel natural).

Dependent Variables

Subjects were asked to answer a number of questions about each product for which they had seen an ad. Different questions about the advertisements were also posed to maintain the cover story. The crucial measure of attitude toward the product consisted of the sum of subjects' ratings of Vilance shampoo on four 9-point semantic differential-type scales (good/bad, satisfactory/unsatisfactory, favorable/unfavorable, high quality/low quality).

Results

The means for each cell on the measure of attitude toward

Vilance shampoo are presented in Table 2. A 2 X 2 X 2 X 2 analysis of variance revealed no main effects nor interactions involving the sex of subject variable so this will not be discussed further. A main effect for the argument quality manipulation, $F(1,223) = 35.41, p < .0001$, indicated that the strong arguments produced more favorable attitudes toward the product ($M = 6.6$) than did the weak arguments ($M = 1.3$). A main effect for the attractiveness variable, $F(1,223) = 8.46, p < .004$, showed that the high attractive models induced more acceptance of the product ($M = 5.3$) than did the low attractive models ($M = 2.7$).

Of most interest in the analysis, however, was a significant Involvement X Arguments interaction, $F(1,223) = 10.84, p < .001$. This interaction revealed that increasing the personal involvement of the advertisement enhanced the importance of the message content in affecting attitudes. When the relevance of the ad was increased, subjects responded more favorably to the ad with strong arguments, but less favorably to the ad with weak arguments. The Involvement X Source interaction was not significant this time though the means were directionally consistent with the findings of Experiment 1.

TABLE 2

EFFECT OF INVOLVEMENT, ARGUMENT QUALITY, AND SOURCE ATTRACTIVENESS, ON ATTITUDES TOWARD AN ADVERTISED PRODUCT

	High Involvement		Low Involvement	
	high	low	high	low
	Attr.	Attr.	Attr.	Attr.
Strong Arguments	9.1	7.0	6.9	3.4
Weak Arguments	.9	-1.2	4.1	1.4

Discussion

Experiment 2 replicated the finding from Experiment 1 that involvement (personal relevance) is an important determinant of the extent to which content-based persuasion will occur. When the advertisement was high in personal relevance to the subjects, the quality or cogency of the arguments presented in the ad had a much greater impact on attitudes toward the advertised product than when the ad was of low relevance. The study did not find strong support for the view that source factors were more important when the ad was low rather than high in personal relevance, however. In retrospect, this effect may not have been strong in this study because how the models looked may have been viewed as a relevant persuasive argument for some subjects! In other words, for the specific product employed (shampoo), the attractiveness of the models (especially their hair) may have served as persuasive testimony for the effectiveness of the product.

The Role of Involvement in Persuasion

Taken together, the results of the two studies strongly indicate that under high involvement, message content is the prepotent determinant of the amount of persuasion that occurs. Less strongly, the studies suggest that under low involvement, non-content factors such as the credibility or attractiveness of the message source are more important. Thus, the present studies provide some evidence that attitude change is determined by different factors under high and low involvement conditions.

In another paper (Petty & Cacioppo 1981) we have argued that a persuasive message can induce attitude change via one of two routes. Under the first, or central route, thinking about issue-relevant information is the most

direct determinant of the direction and amount of persuasion produced. Attitude changes induced via this route tend to be relatively permanent and predictive of subsequent behavior. Under the second, or peripheral route, attitude change is the result of non-content cues in the situation. Changes induced via this route tend to be relatively temporary and are not highly predictive of subsequent behavior (see review by Cialdini et al., 1981).

According to this framework, involvement is a prime determinant of whether or not an attitude change is induced via the central or the peripheral route. The experiments reported here as well as the results of other recent studies are consistent with the view that under low involvement conditions, persuasion may typically be governed by such peripheral cues as source characteristics, concerns about desirable self-presentation, and/or one's social role, whereas under high involvement, persuasion may be governed more by message content factors such as the number, quality, and/or accuracy of the message arguments presented (cf., Cacioppo & Petty 1980, Chaiken 1980, Cialdini et al. 1976).

The level of involvement is not the only determinant of the route to persuasion, however. In addition to having the necessary motivation to think about issue-relevant argumentation, the message recipient must also have the ability to process the message if change via the central route is to occur. Thus, if involvement is high (and the person is motivated to think about the message content), but the arguments are too complex for the person to understand, or if too many distractions prevent issue-relevant thought, then the central route cannot be followed.

Finally, we note that attitude change via the central route is a very difficult way to change a person's attitudes. First, the message must show some personal relevance to the recipient. Second, the person must have the ability to process the message content. Third, the message must present arguments that elicit primarily favorable thoughts. If the recipient is able to counterargue the message, then increasing involvement will not facilitate persuasion. If a change can be produced via the central route however, the benefits are clear--the attitude change will tend to persist and be predictive of subsequent behavior. An alternative strategy is to induce attitude change via the peripheral route. Since the peripheral route induces only a temporary change, it will be necessary to constantly remind the recipient of the cue (e.g., attractive source) upon which the new attitude is based. Lutz (1979) provides the example of a person who drives Hertz Rent-a-Cars, not because the person has thought about the attributes of the company (central route), but only because he has been constantly reminded that O. J. Simpson endorses the company (peripheral route). If the favorable attitude about Hertz had been based on a full consideration of the positive features of the company, the favorable attitude would likely persist on its own. Since the favorable attitude is based on a positive peripheral cue however, the favorable attitude persists only so long as the cue remains salient (accomplished through advertising repetition). Such continually repeated positive cues may be sufficient to get a person to try the advertised product. Interestingly, once the person has tried the product, it may become more personally involving and may make the person more likely to think about the content of future advertisements about the product. In this manner a peripheral change can lead to a central one.

THE DIMENSIONS OF ADVERTISING INVOLVEMENT

Andrew A. Mitchell, Carnegie-Mellon University

Abstract

A conceptual definition of involvement and a conceptual model of how involvement affects the information acquisition process is presented. This definition views involvement as an internal state of an individual with both intensity and directional properties. As such, it is one of many different variables that may affect the information acquisition process. This definition and model is then used to discuss alternative definitions of involvement and previous research examining the effect of involvement on communication processes.

Introduction

Interest in understanding the effect of involvement on communication processes has been increasing in recent years. There seems to be a general understanding of communication effects under conditions of "high involvement" and a general agreement that communication effects under conditions of "low involvement" are different from those under "high involvement". However, these effects under "low involvement" conditions are not well understood. Recently, there have been a number of attempts to examine these differences experimentally (e.g., Petty and Cacioppo 1979, Mitchell 1980, Mitchell, Russo and Gardner 1980), however, the "involvement" manipulations differ in these studies so it is difficult to understand the results.

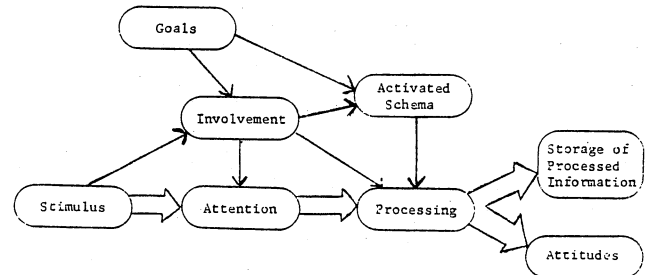

Much of the confusion surrounding involvement and its effect on communication processes seems to center on our failure to understand conceptually what involvement is and how it may affect the information acquisition process. In this paper, I will attempt to clarify this misunderstanding. In the next section I will present a definition of involvement and a conceptual model of how involvement affects the information acquisition process. Next, I will discuss our research which has been based on this model and then use the model to discuss previous research examining the effect of involvement on communication processes and alternative conceptual definitions of involvement.

Conceptual Model

In a previous paper, I defined involvement as an individual level, internal state variable whose motivational properties are evoked by a particular stimulus or situation (Mitchell 1979). As such, it has two dimensions, intensity and direction. Consequently, in discussing involvement in a particular context, we must define both the level of involvement (e.g., high vs. low) and also the direction of involvement (e.g., directed at the advertised brand or at an element of the advertisement).

A conceptual model of the effect of involvement on the information acquisition process is presented in Figure 1. The double arrows indicate the critical stages of the information acquisition process that affect attitude formation and the retrieval of processed information from long term memory. These critical stages are attention and processing. Attention is conceptualized as having capacity limitations (e.g., Kahneman 1973) which causes individuals to focus their cognitive resources on a limited number of stimuli in the environment. In processing information, then, one decision individuals must make is which stimuli to attend to and the amount of attention to devote to each stimuli.

FIGURE 1
CONCEPTUAL MODEL

The second stage is processing. Here individuals interpret the information from the environment, make inferences and evaluate the information. Numerous theories from cognitive psychology indicate that how individuals process information affects their ability to retrieve the information at a later point in time (Mitchell 1980). For instance, the depth of processing approach suggests that the use of semantic processing and the amount of elaboration that occurs during processing enhances the ability to retrieve the processed information (e.g., Craik and Tulving 1975, Craik 1979). Other theories hypothesize that other dimensions of processing affect recall (e.g., Paivio 1971, Nelson 1979). Although there is general agreement that the type of processing that occurs during exposure to a stimulus affects the recall of that stimulus, there is currently disagreement as to exactly what dimensions of processing affect recall.

There is also considerable research that indicates that the type of evaluative processing or the type of cognitive responses generated during exposure affects attitude formation and change (e.g., Greenwald 1968, Wright 1973, 1980). For instance, counterarguments reduce the favorableness of the attitudes that are formed while support arguments enhance their favorableness. In summary, then, the two critical stages in the information acquisition process are attention and processing. These two stages will affect what information can be retrieved from long term memory and the formation and change of attitudes.

The factors which affect attention and processing are the stimulus (e.g., advertisement) and the goals of the individual while exposed to the stimulus. These factors, in turn, determine the level and direction of involvement and the particular memory schema that is used to process the information. Here we define memory schema as an organized set of information about a concept in long term memory (e.g., Rumelhart and Ortony 1978).

To illustrate the model, assume that a number of individuals are exposed to an advertisement for a new fuel efficient automobile. In the advertisement, the automobile is shown on a dock surrounded by a number of sailboats. If an individual, for instance, was planning to purchase a small fuel efficient automobile in the near future and had not decided which brand to purchase, he or she would probably be very interested in this product and may be actively searching for information about the various alternatives on the market. Consequently, this individual would probably devote full attention to the advertisement and activate a memory schema that contains information about

fuel efficient automobiles so that he or she can critically evaluate the information in the advertisement. As a consequence of this processing, the information about the new fuel efficient automobile would be organized into a tightly integrated knowledge structure and, in most cases, an evaluation of the new automobile would be formed.

Another individual, however, may not be interested in purchasing an automobile or even obtaining information about new brands of fuel efficient automobiles. When this individual is exposed to the same advertisement, he or she may be attracted to the picture of the sailboat in the advertisement due to an interest in sailing. This individual might also devote full attention to the advertisement and may skim part of the copy, however, he or she would probably activate their memory schema for sailboats in processing information from the advertisement. This would result in a different type of processing than in the first case. Since the individual did not activate the memory schema that contains information about fuel efficient automobiles, he or she would not have comprehended the message (Rumelhart and Ortony 1978) and would generate few, if any, counterarguments or support arguments. As a result, he or she may have acquired some information about the advertised car, but it would be much less information than in the previous example and it probably would not be tightly organized into a knowledge structure about the advertised automobile. In addition, the individual probably would not have formed an evaluation of the automobile during exposure to the advertisement.

Finally, a third individual may have little interest in automobiles or sailboats and, therefore, this individual would probably devote little attention to the advertisement and would probably do little active processing of the information in the advertisement. In this case, the individual may be unable to retrieve any information about the new automobile and may not be aware of its existence. In summary, then, the content of the stimulus and the goals of the individual determine the amount and direction of involvement during exposure to the advertisement. The intensity of the involvement determines how much attention is devoted to the advertisement. The direction of the involvement determines which memory schema is activated which, in turn, determines the type of processing that occurs during exposure.

Our Research

In our research (Mitchell 1980, Mitchell Russo and Gardner 1980), we have directly manipulated processing strategy and attention levels to examine the resulting effects on attitudes, intentions and the retrieval of brand related information from long term memory. In this research, we differentiate between a brand and a nonbrand processing strategy. A brand processing strategy involves the active processing of brand information from an advertisement to either form an evaluation of the brand or acquire information about the brand. A nonbrand processing strategy involves the processing of information from the advertisement to achieve some other goal. This may be caused, for instance, by the use of an attention getting device such as an attractive model in the advertisement.

To manipulate processing strategy, we instruct subjects to either examine the advertisement to form an evaluation of the advertised brand (brand processing strategy) or to evaluate the effectiveness of the advertisement (nonbrand processing strategy). For the latter manipulation, we provide subjects with a set of criteria to use in evaluating the effectiveness of the advertisement. These two different instructions presumably result in the activation of different memory schema for use in processing the information.

In our initial study, (Gardner, Mitchell and Russo 1978, Mitchell, Russo and Gardner 1980), we examined the effect of the two different processing strategies with high attention levels on attitudes and the retrieval of information from long term memory. The subjects in each condition were shown advertisements for four new brands in four different product categories. The results indicated that subjects executing a brand processing strategy were able to retrieve more product related information faster and at a greater level of accuracy than subjects executing a nonbrand processing strategy (Mitchell, Russo and Gardner 1980). In addition, subjects using a brand processing strategy formed less favorable attitudes toward the advertised brands. Although the subjects using a brand processing strategy generated almost twenty times as many counterarguments, support argument and support derogation statements as subjects using a nonbrand processing strategy, these differences only partially explained the differences in attitudes. More specifically, the use of the number of counterarguments, support arguments and source derogations as covariates did not eliminate all the reliable difference in attitudes between the two groups. These results suggest the possibility that other mediators may affect attitude formation in these conditions.

In a second study, these two different processing manipulations were used along with two different manipulations of attention levels (Mitchell 1980). For one attention level manipulation, subjects were shown advertisements for new products and were instructed to execute a brand processing strategy while watching a red and a blue light that randomly flashed at the rate of approximately 25 flashes per second. Subjects were instructed to raise their left hand whenever one of the two lights flashed. The second attention level manipulation required the subjects to count backward by three's from a three digit number while examining the advertisements. The subjects in each condition saw the same eight advertisements for new brands in eight different product categories. The results indicated differences in attitudes and the amount of product related information retrieved from long term memory between all conditions except the nonbrand processing condition and the second attention level manipulation where subjects had to count backward by three's.

These results suggest that differences in involvement may result in three different types of information acquisition processes. One process is caused by a "high involvement" condition and two are caused by "low involvement" conditions (Figure 2). Here "high involvement" refers to high interest levels in the advertised brand. Under the "high involvement" condition, individuals devote all their attention to the advertisement and execute a brand processing strategy. Consequently, they will critically evaluate the brand information in the advertisement and will, generally, form an overall evaluation of the advertised brand during exposure to the advertisement. This means that their verbal thought processes during exposure to the advertisement will contain a large number of counterarguments and support arguments.

Under the first "low involvement" condition, individuals will also execute a brand processing strategy, however, this strategy will be executed with reduced attention levels. This will generally result in a reduction in the number of counterarguments and support arguments generated which, in turn, will frequently result in a difference between this condition and the "high involvement" condition in the attitudes that are formed. Under this condition, then, individuals will comprehend the message since the proper schema is activated, but they will not be as critical of the information as they were under conditions of "high involvement".

FIGURE 2
ALTERNATIVE MODELS OF INFORMATION ACQUISITION
UNDER DIFFERENT INVOLVEMENT CONDITIONS

Model I: Information Acquisition Under Conditions of "High Involvement"

Model II: Information Acquisition Under Conditions of "Low Involvement"

Model III: Information Acquisition Under Conditions of "Low Involvement"

Finally, the second "low involvement" condition occurs when individuals either execute a nonbrand evaluation strategy or there are severe attention deficits. There will be few, if any, counterarguments or support arguments generated and the individuals will not totally comprehend the message. They will, however, acquire some information about the advertised brand.

These three different information acquisition processes should cause differences in the amount, content and organization of information about the advertised brand in memory. In the previously mentioned study (Mitchell 1980) subjects in the nonbrand brand processing condition and the second attention level condition could recall significantly less information about the advertised brands than subjects in the brand processing condition and the first attention level condition. It also took them longer to verify statements about the attributes of the advertised brands and their evaluation of them. No differences were found on these two measures between the brand strategy condition and the first attention level condition or the nonbrand strategy condition and the second attention level condition. Since attitudinal differences were found between the first two conditions, however, we might expect differences in the content of the information that would be recalled.

In summary, our conceptualization of involvement and our research suggest that differences in involvement may result in three different types of information acquisition processes -- one caused by a "high involvement" condition and two by "low involvement" conditions. In addition, we believe that the latter two processes may be caused by factors other than involvement. One of these may be a lack of knowledge about the topic of the communication.

Alternative Approaches To Involvement

There have been a number of articles over the last ten years either discussing the effect of involvement on the reception of communications or experimental studies which manipulate involvement and examine the resulting effects. As mentioned previously, these conceptualizations and manipulations have generally differed. In this section, I will discuss these alternative manipulations and conceptualizations using the model presented in the previous section.

Conceptual Approaches

Krugman: In his original article, Krugman (1965) suggested that the cognitive processes that occur during exposure to television advertisements were similar to those that occur during the learning nonsense syllables. As evidence of this similarity, Krugman mentioned that the recall of three consecutive television commercials displays the same U shaped relationship as the recall of a series of nonsense syllables -- strong primacy and recency effects. He further hypothesized that television advertising produces subtle shifts in our perceptions of brands which result in changes in the saliency of the different attributes of the product. In this article, and in a second article (Krugman 1967), he defines involvement as the number of "bridging experiences, connections or personnel references per minute that the viewer makes between his own life and stimulus", not as the "amount of attention, interest or excitement".

This definition of involvement differs from the one presented here in that Krugman defines involvement as one of the dimensions of the type of processing that occurs during exposure to the advertisement. In contrast, I define involvement as a particular state of the individual at a point in time. Our state variable conceptualization of involvement affects the type of processing that occurs during exposure, however, it is not the only variable that may affect it. The amount and type of knowledge that an individual has and the memory schema that is activated during exposure also affects the resulting processes. Therefore, it is entirely possible that according to our definition an individual may be highly involved, however, if this person has little knowledge about the advertised product, the resulting process might be a low involvement one according to Krugman's definition.

In general, we believe that information acquisition under the second low involvement condition is similar to the one Krugman describes in his original paper. Under our second low involvement condition individuals acquire information about the advertised brand but do not actively organize this information into a conceptual understanding of the product. At some later point in time, something may trigger the individual to organize this information about the advertised brand, and at this point, an attitude may be formed.

In an experiment which I am currently conducting, we find that subjects who executed a nonbrand processing strategy during exposure to a set of advertisements lose information more rapidly during a two week interval after exposure than subjects that executed a brand processing strategy during exposure to the same advertisements. This result also seems to be consistent with Krugman's conceptualization of what should occur under low involvement conditions.

Greenwald, Leavitt and Obermiller: Greenwald, et. al (1980) also define involvement as a process and suggest that there may be a "high involvement" process and two "low involvement" processes. Their "high involvement" process agrees with my conceptualization of information acquisition under conditions of "high involvement", however, we differ on the other two processes. The first "low involvement" process proposed by Greenwald, et. al (1980) seems to contain both of our information acquisition processes under conditions of "low involvement". We, however, believe that the distinction we make is an important one since, as discussed previously, these two processes result in differences in the amount, content and organization of the processed information in long term memory and may result in attitudinal differences.

The second "low involvement" process suggested by Greenwald, et. al (1980) is based on the "mere exposure"

literature (Zajonc 1980). This literature indicates that attitudes may be formed toward a stimulus even though the individual cannot determine, at better than chance levels, whether he or she has seen the stimuli (Wilson 1979). Greenwald, et. al (1980) refer to this as a pre-attentive process.

Although these ideas are interesting, they have yet to be demonstrated with complex as opposed to simple stimuli. Part of the problem with examining information acquisition under these conditions is defining exactly what non-attention means in terms of experimental manipulations. Kellogg (1980), for instance, has recently suggested that individuals can recognize unattended stimuli. This conclusion is based on the results from a series of experiments where subjects looked at pictures of faces while performing a complex multiplication task. Kellogg found that under these conditions his subjects could recognize the pictures at greater than chance levels, however, there was a decrement in recognition performance compared to when the subjects looked at the faces under conditions of full attention.

Problems arise in these types of studies, however, since individuals can acquire information through different channels. Research, for instance, has indicated that individuals have both a verbal and visual channel for acquiring information (e.g., Brooks 1968) and a single distractor task may not use up the capacity of both channels. Kellogg (1980), presents evidence that his complex multiplication task used up the capacity of the verbal channel, however, it is not clear whether his instructions to produce a mental image of the task used up the capacity of the visual channel.

In the experiment discussed previously, for instance, we found that when the advertisements contained visual information, our subjects formed different attitudes under the second attention level condition than a control group that did not see the advertisements (Mitchell 1980). This did not occur for advertisements that contained primarily verbal information. Consequently, in order to examine whether learning can occur under these conditions, we need to define more precisely what we mean by nonattention during exposure.

Issue Involvement

Concern with the effects of issue involvement on persuasion goes back at least as far as the research by Hovland and Janis on communication effects (Hovland, Janis and Kelley 1953). This early research led to the development of social judgment theory which provides an explanation of the effect of issue involvement on persuasion (Sherif, Sherif and Nebergall 1965). According to this theory, individuals that are highly involved with an issue will have large "latitudes of rejection" and will, therefore, be more likely to reject a persuasive message on this issue.

Recently, Petty and Cacioppo (1979) examined the effect of issue involvement on the number of counterarguments and support arguments generated during exposure to a persuasive communication. In two different experiments, Petty and Cacioppo (1979) manipulated issue involvement by presenting subjects with a persuasive communication advocating a change in coed visitation hours. In the high involvement condition, these changes were advocated for the student subjects' own university, while in the low involvement condition the change was advocated for another university. The other manipulations included the direction of change advocated and the strength of the arguments supporting the change. As might be expected, increased involvement enhanced persuasion for the proattitudinal message (i.e., increase visitation hours) and reduced persuasion for the counterattitudinal message (i.e.,

decrease visitation hours). Increasing involvement also enhanced persuasion for the message with the strong arguments even though the message was counterattitudinal, but reduced persuasion for the message with weak arguments. Perhaps one of the most interesting findings was that under low issue involvement conditions, the correlations between cognitive response measures (e.g., counterarguments) and attitudes were considerably lower than under conditions of high involvement (average absolute values of .29 vs. .69).

In terms of the model that was presented here, the topic of the message affected the subjects' involvement with the message. This, in turn, resulted in differences in attention levels and processing strategies. In each case, the authors found that low issue involvement resulted in a general reduction in the amount of evaluative processing (i.e., number of counterarguments and source arguments) that occurred. This indicates that the involvement manipulation used in these experiments resulted in information acquisition under our first low involvement condition.

As mentioned previously, they also found that the magnitude of the relationships between the number of counterarguments and support arguments and the resulting attitudes were greater under the high involvement manipulation than under the low involvement manipulation. It is interesting to note that in our study (Mitchell, Russo and Gardner 1980), we found that the magnitude of the relationship between a measure of attitude and attitudes predicted from the Fishbein model was greater with the brand processing strategy than with the nonbrand processing strategy. In other studies, we have generally found that the number of counterarguments and support arguments and predicted attitudes from the Fishbein model explained the same variance in independent measures of attitudes (Mitchell 1981). Therefore, it would seem that the type of semantic processing that occurs during exposure to a communication and the semantic information in memory after exposure explains more of the variance in attitudes when information is acquired under conditions of high involvement as opposed to low involvement. This suggests that either other mediators of attitude formation and change may be operating under these latter conditions or that the resulting attitudes may be less reliable.

Media Involvement

Krugman (1965, 1966) has suggested that, based on his definition of involvement, the media used in advertising a product determines the resulting level of involvement during exposure. According to Krugman, television advertising results in low involvement conditions while print results in high involvement conditions.

Wright (1974) tested this hypothesis by examining the effect of providing the same information both visually (print) and auditorily (radio) and found that his subjects generated fewer counterarguments and support arguments with the audio message as opposed to the visual message. Wright argued that these differences occurred because individuals do not have the opportunity to verbally respond to audio messages since they cannot control the rate at which they receive information. In other words, capacity constraints limit the amount of verbal processing that occurs during an audio message. It should be noted that if Krugman is correct in his hypothesis concerning the similarity in the type of processing that occurs during exposure to a television commercial and the processing that occurs during the learning of nonsense syllables, then Wright's explanation is consistent with the currently accepted explanation for the finding of primacy and recency effects in verbal learning experiments.

Much of this argument is based on how involvement is conceptualized. As mentioned previously, Krugman views involvement as a process -- essentially the type of processing that occurs during exposure to a communication. If, however, involvement is viewed as a state variable and only one of many variables that may affect the type of processing that occurs during exposure to an advertisement, it would be possible for someone to be highly involved with a television advertisement. However, because less time is available to process the information, he or she may execute a different type of processing than would occur if the same information is presented in print.

Brain Wave Activity and Involvement

In a provocative article, Krugman (1977) suggested that the processing of information from television advertisements may be primarily a right brain activity while the processing of information from print advertisements may be primarily a left brain activity. Based on this hypothesis, he also suggested that the primary effect of most television advertising may be the storing of visual images in the right hemisphere of the brain. Under these conditions, individuals would not necessarily be able to recall specific television commercials, however, individuals would be able to recognize whether or not they had seen a television commercial. Supposedly, according to Krugman, their recognition of a specific commercial may have an effect at the point of purchase.

To test this hypothesis, Appel, Weinstein and Weinstein (1979) measured the brain waves of subjects exposed to high recall and low recall television advertisements that were presented three times to each subject. The results indicated that advertisements with higher recall scores generated higher levels of brain wave activity (e.g., more seconds of alpha waves), however, there was no difference in the amount of brain wave activity between the left and right hemispheres. Krugman (1980), however, after re-examining the data, found brain wave activity in the left hemisphere declined with repetition, but brain wave activity in the right hemisphere remained constant with repetition. In a later study, Weinstein, Appel and Weinstein (1980) reported no difference in the amount of brain wave activity in the left and right hemispheres for subjects exposed to print and television advertisements. Magazine advertisements, however, generated a higher level of brain wave activity in both hemispheres as opposed to television advertisements.

These results seem to indicate that the amount of brain wave activity in each hemisphere is generally the same during exposure to advertisements in both television and print. There may, however, be differences after a number of repetitions. In addition, magazine advertisements seem to generate more brain wave activity. If there is a strong relationship between brain wave activity and the amount of cognitive response generated, and I suspect that there is, these latter results would tend to confirm the findings of Wright (1974). Cacioppo and Petty (1979), for instance, found a positive relationship between a number of physiological measures (e.g., oral muscle, cardiac and respiratory activity) and the number of counterarguments and support arguments generated.

Discussion

In this paper, I have presented a definition of involvement and a conceptual model of how involvement affects the information acquisition process. This definition, which defines involvement as an internal state variable whose motivational properties are evoked by a particular stimulus, differs from other definitions which define involvement in terms of the type of processing that occurs during exposure to an advertisement. Under the

conceptualization of involvement presented here, involvement is only one of many possible causes of these processes. Others are the amount of knowledge that an individual has about the topic of the communication and the opportunity to cognitively respond to the communication. In general, much of the confusion in the literature concerning involvement seems to center on different conceptualizations of involvement.

We have also suggested that different levels of involvement may cause three different types of information acquisition processes. One is caused by high involvement and two by low involvement. The issue involvement manipulation used by Petty and Cacioppo (1979) seems to have resulted in information acquisition under the first low involvement condition, while we suggest that Krugman (1965) is essentially discussing information acquisition under our second low involvement condition.

One interesting effect of involvement on the information acquisition process that has been found in two different experiments is a reduced relationship between semantic information and attitudes. Petty and Cacioppo (1979), found smaller correlations between counterarguments and attitudes and support arguments and attitudes under conditions of low issue involvement as opposed to high issue involvement. Mitchell, Russo and Gardner (1980) found smaller correlations between predictions from the Fishbein model and attitudes under a nonbrand processing strategy as opposed to a brand processing strategy. These lower correlations may occur for two different reasons. First, attitudes formed under conditions of low involvement may have lower reliability. This would result in lower observed correlations. Second, other mediators of attitude formation may have a greater effect under these conditions. Clearly, additional research is required to both verify this effect and, if valid, to determine its cause.

Finally, it should be noted, that the examination of factors affecting the information acquisition process can occur at different levels. Petty and Cacioppo (1979) and Wright (1974), for instance, examined the effects of message involvement and modality while Mitchell (1980) and Mitchell, Russo and Gardner (1980) examined the effects of different attention levels and processing strategies. Mitchell (1981) has referred to the latter manipulations as Level One variables affecting the information acquisition process while the former are called Level Two variables. Obviously, research at both levels is required to understand communication effects, however, it may be very difficult to obtain Model III information acquisition processes with Level Two variables in the laboratory. This may occur because knowledge that they are participating in a laboratory experiment may automatically raise the involvement level of subjects so that only Model I or Model II processes may occur.

LOW INVOLVEMENT: A SECOND LOOK

Harold H. Kassarian, University of California, Los Angeles¹

Abstract

Low involvement decision-making seriously challenges the cognitive orientation of present-day consumer research. However, product involvement may well be more complex than assumed thus far in that there may be an interaction effect with individual or personality characteristics. This paper proposes a six-fold classification of involvement including both high and low product involvement and also high and low involved personality types.

Introduction

In most fields of endeavor, new ideas are occasionally introduced which profoundly alter the prevailing status quo. In the physical sciences these may actually alter conceptions of physical reality - for example, the strange ideas of Copernicus thoroughly discredited the earlier views of philosophers and theologians alike. The systematic relationship of the ideas of men like Maxwell, Hertz and Einstein severely limited, and perhaps crippled, Aristotelian and Newtonian thinking. And in turn, what was to become known as field theory in physics had a profound effect on conceptualizations in biological and social sciences as earlier viewpoints crumbled.

In art and architecture, literature, humanities and music, similar turning points can be pointed out. For example, Elvis Presley and the Beatles altered musical conceptions as New Orleans Jazz had done earlier. Similarly in psychology, the contributions of Freud and his followers succeeded in destroying earlier views on the behavior of man as the unconscious and the impact of society on the mind were emphasized.

In less far-reaching areas of inquiry such as consumer behavior, similar patterns are evident. The elegant, yet simple, utility theory of economics was to give way to the psychoanalytically oriented motivation researchers. In turn, the clinical complexity of Freud was to make room for Hullian conceptions of learning theory. Even the idea of determinism began to be challenged with the introduction of mathematical learning theory into the field, culminating in Bass's (1974) proclamation that "man is substantially stochastic." And through the influence of social psychology and Bauer's (1964) claim of the "active audience," cognitive theory began to reign imperial - the notion, "... of a highly rational goal-striving, problem solving, information seeking, extracting, processing consumer ..." (Markin and Narayana, 1975). Topics such as attitude decision rules, as well as virtually every flow chart model of consumer decision-making have unquestioningly joined the "cognitive revolution" (McGuire 1976).

Perhaps it is too early to make the claim, but it may well come to pass that the cognitive view may also have to be modified. The concept of low-involvement might profoundly alter our present conceptions of the consumer.

Two Fields of Decision-Making

There is certainly no argument that under some conditions, at least for the purchase of some categories of goods and services, consumers do behave as information processing, problem solving, cognitive individuals reaching for a reasoned decision. These, of course, are the high involvement situations involving important, expensive, high risk, ego-related or value-expressive products. Actions and decisions are often highly sophisticated. And these decisions we have studied. We have analyzed, dissected, mapped and flow-charted the cognitive processes assumed to exist.

The problem is that the world of the consumer consists of more than highly involved decisions. In fact, very few of the hundreds of decisions made daily by the consumer are of an involved nature. In others, the low involvement decisions, the consumer unconcernedly purchases and consumes the product, tries new products, switches brands, obviously ignores promotional activities and worries about the important events in his or her life - the automobile's need for repairs, the children's grades in school, irritants at work or what have you.

In the last few years, numerous empirical and conceptual papers and a splendid review by Olshavsky and Grandbois (1979) clearly point out that the behavior of the consumer toward the high involvement, high risk, important product is simply different than toward the unimportant, low commitment, trivial product. Research in the future is simply going to have to take into account these two different sets or fields of decision making. For most types of consumer research the distinction will have to be made as to whether the products under study are of a high involvement nature or low involvement for the sub-set of respondents that comprise the subject pool. For example, Ray and his colleagues (1973) have proposed two hierarchies of effects, one for low involvement and another for high involvement situations.

Research on the hierarchy of effects in marketing communications is an excellent example of the fact that cognitive activity for low involvement and high involvement are simply different and that one cannot generalize research results from one situation to the other. Thus, research must measure the concept of involvement first, then turn to the hypotheses at hand. At this point it is unfortunate that a simple instrument or tool has not yet been developed to measure the concept of involvement but if in fact, "necessity is the mother of invention," that will come in time - for the measure of involvement is unquestionably a necessity - one that can no longer be ignored (See Hupfer & Gardner 1971).

Other topics in consumer research that may be seriously affected by the concept of low involvement are presented in Table 1.

The Involved Consumer

Segmenting products by the level of involvement although seemingly essential, may not fully account for all of the variance associated with the concept of high and low involvement. It may come to pass that we discover or personality variable related to the concept.

¹Written while visiting professor, Copenhagen School of Business Administration and Economics, Denmark.

Table 1

TOPICS HYPOTHESIZED TO BE RELATED TO LEVELS OF INVOLVEMENT

- Advertising Effectiveness
- Attitudes and Beliefs
- Attitude Change, Formation and Immunization
- Attribution Theory and Self Perception
- Brand Loyalty, Preference, Choice
- Cognitive Dissonance
- Cognitive Response
- Consumer Satisfaction
- Deceptive Advertising
- Decision Rules
- Family Decision Making
- Halo Effects
- Hierarchy of Effects
- Information Acquisition
- Information Processing
- Innovation and Diffusion
- Models of Consumer Behavior
- Perceived Risk
- Personal Influence
- Personality Correlates
- Persuasion
- Physiological Measures
- Political Marketing
- Pre-Purchase Anxiety
- Price and Packaging Research
- Reference Groups
- Repetition in Advertising
- etc.

It is undeniable that independent of the product class, there are some persons that tend to be more involved in the consumer decision process. They may be the addicted reader of *Consumer Reports*, those who pay greater attention to advertising and personal influence, and to the business and consumer sections of the newspaper. Some individuals may well be more price conscious, more alert to brand differences, generally more capable of discriminating quality differences, the more alert, the more conscious, the more interested and involved consumer. The category of person might include the wise housewife, the consumer activist, marketing people and professors of consumer behavior, among others

The Non-Involved Consumer

Equally evident is the fact there are other individuals who do not wish to concern themselves with marketing and buying activity. These might be individuals holding strong theoretical or aesthetic values who are simply oblivious to the practical affairs of the day to day world including marketing, advertising, consumption of goods, or to the accumulation of wealth. They have other interests and other concerns and just do not care and are uninvolved about consumer activities. This group might be termed detached individuals, those who put an emotional distance between themselves and the marketplace.²

It might also include the "know-nothings" of days past, the uneducated, and those who simply care very little about anything outside of their self-centered orbit. This group might very well be the utterly "no opinion" group on political polls, those who do not respond to mail questionnaires no matter what the issue, and refuse to try

²The term "detached type" seems particularly descriptive but does necessarily imply that it is similar to Horney's Detached Orientation (1937, 1945) nor necessarily measurable on Cohen's CAD Scale (1968).

free samples, try new products, or be interested in any of the issues that are of interest to this audience.

Hence the low involvement consumer consists of two groups. Those that are concerned about more significant problems and issues than consumer topics and those that can be best described as Know Nothings.

Moreover, in consumer research, an interaction effect between product involvement and individual involvement may exist suggesting perhaps a six-fold classification schema as presented in Table 2.

Table 2

CLASSIFICATION OF INVOLVEMENT

		Situation Effect or Product Involvement	
		High	Low
Individual or Personality Factors	High Involvement	Much of Consumer knowledge as it exists today	Typical low Involvement Research
	Low Involvement "Detached Type"	Minimal interest but narrowly and intensely focused	Oblivious to Product Issues Other Interests
	Low Involvement "Know-Nothing"	Choice determined by: availability packaging affordability	Don't know, Don't care and No opinion

The upper left hand cell - the high involvement personality, high involvement product group - consists of those people and behavior patterns that have been heavily studied in the past. Research on information processing, attitudes and consumer behavior models of decision making, is discussing this sub-set of consumers. They are the ones that fill out questionnaires, allow researchers to examine their behavior, and sit still for the numerous inane tasks that are required of them in experimental and descriptive research.

The upper right hand corner - the high involved consumers with low involved products - refers to the field of low involvement research as it has evolved to this point. Interested, concerned, cooperative subjects that have been presented with products in which they simply are not involved. The low involvement products may include a variety of consumer goods, politicians, causes, or a host of other objects and issues about which the individual simply is not concerned.

The detached individual with a highly involved product perhaps causes the greatest conceptual difficulty. He or she generally is unconcerned about the practical affairs of marketing and yet from time to time a product or issue may emerge which is of great importance. In this case, it is hypothesized that the embryonic interest, although perhaps temporarily intense, would be extremely narrowly focused. Once the politician is elected (or defeated), the issue is resolved or the product purchase

decision consummated, he returns to his basic state of apathy and detachment.

The lower left hand cell consists of the "know-nothings" who from time to time may be placed in a position where they simply must become involved in a product decision. Under these conditions the decision process probably is not the analytic, cognitive approach of the high involvement or detached type, but choice is determined by what is most easily available or whether or not one simply has enough money to pay for the object. The influence of attractive packaging or a glib salesman may be far more significant than a cognitive analysis of the product characteristics. "But it looked so pretty, and the man was no nice," may better describe the decision process than compensatory or lexographic decision rules.

The final group in the lower right hand corner can best be described by the terms, "don't know," "don't care," and "no opinion." This group is seldom, if ever, concerned about the affairs of the world - be it politics or canned spinach. Under a low involvement product condition, their contribution to consumer research primarily consists of filling the "no opinion" cells of a research design and contributing to the error term in any statistic.

Perhaps if research on low involvement is to be meaningful, the personality characteristic of involvement should be accounted for in research designs. Typically the "know-nothings" particularly in a low involvement product condition are naturally eliminated from research designs by their unavailability, but the differences between detached individuals with high involvement products and high involved persons with low involvement goods may be confounded in data analysis at present.

Space and time constraints do not allow for further elaboration at this point but such a personality - product involvement interaction effect seems quite conceivable and researchable, once tools or instruments are available for the measurement of product involvement and personality types.

Conclusion

If in fact involvement is an important topic, we should see its effects permeating research other than in the usual cognitive processing type of study. For example, the work of Kroeber-Riel and his colleagues on psychobiology seems particularly amenable and relevant (Kroeber-Riel 1979, 1980; see also Ryan 1980). Furthermore, the fascinating research being carried out by Flemming Hansen and his colleagues seems to be taking these types of distinctions into account (Hansen and Lundsgaard 1981, Hansen (In Press)). Hansen reports in his review of right-brain, left-brain lateralization research that in low involvement situations right-brain processes dominate whereas higher degrees of involvement give rise to left-brain processes. Thus, under high involvement conditions, information processing and deliberate choice-making occur. Under low involvement conditions information is received holistically and choices made without any high degree of awareness. He continues that under low involvement the number of exposures needed before a sufficient amount of learning has occurred may be greater when right-brain processes dominate.

In addition, there is some evidence to indicate that there may be individuals who are right-brain dominated and others who are left-brain dominated. The Hansen and Lundsgaard paper to be presented at this conference on Sunday morning presents the introductory report of their attempt to measure this variable with a paper-and-pencil test. If their stream of research is successful and a reliable-valid instrument emerges for measuring right or left brain domination, that approach would probably be superior to the

high-low involvement personality characteristic proposed here. In either case, it is becoming more and more evident that high and low involvement is not merely a product or situational characteristic but in some way involves the individual either on the molar level of overall disposition or on a more molecular or physiological level such as brain hemisphere research.

In summary, the simple concept of involvement off-handedly introduced by Krugman some years ago, may well qualify as one of the more important scientific ideas to emerge in consumer research in recent years. If I am correct, the topic should have an impact that will alter many if not most of our conceptions of consumer behavior models and our middle range theories and seriously challenge the supreme role of cognitive theory in our thinking.

ATTITUDE STRUCTURE AND SEARCH:
AN INTEGRATIVE MODEL OF IMPORTANCE-DIRECTED INFORMATION PROCESSING

Morris B. Holbrook, Columbia University
David A. Velez, Columbia University
Gerard J. Tabouret, Columbia University

Abstract

In spite of extensive research on multiattribute attitude models and information-acquisition paradigms, the linkage between these two important facets of buyer behavior is not yet well understood. Theory and previous studies suggest an integrative model of importance-directed information processing. This model proposes (1) that attribute importance is positively related to the extent and order of search and (2) that the resulting set of acquired cues serves as the basis for attitude. The results suggest both the feasibility of a questionnaire-based search task and the desirability of a more integrative approach to the study of attitude formation.

Introduction

Extensive progress has recently been made by consumer researchers in understanding the structure of attitudes that shape brand choices and in tracing the process by which information is acquired as a basis for preference formation. Too often, however, studies of attitude structure and information acquisition have proceeded independently. As a result, the connection between these two crucial phenomena has not yet been fully investigated.

More specifically, multiattribute attitude research has tended to focus primarily on the static structure of attitude while neglecting the process by which new informational inputs are incorporated into the determination of affect (Holbrook 1978). By contrast, research on information acquisition has typically dealt in great detail with the search process without systematically examining its presumed impact on brand evaluation (Holbrook and Maier 1978). In short, each approach has, in its own way, been somewhat one-sided. As a result, the linkage between attitude structure and information acquisition remains a vitally important area of consumer research with neglected potential for integration. Accordingly, the main purpose of the present paper is to propose and test a simple integrative model of information processing.

A Model Of Importance-Directed Information Processing

Importance and Search

The Principle of Parsimony (Haines 1974) argues that limited cognitive capacity forces problem solvers to adopt heuristics restricting their attention to the minimum amount of data necessary for satisficing decisions (Bettman 1974; Payne 1976; Wright 1973, 1974). Plausibly, one such heuristic might be to select cues bearing on those aspects of the decision regarded as most important. Indeed, such a search strategy would be consistent with the lexicographic decision model's assumption that information on various brand attributes will be processed in order of their perceived importance (Payne 1976; Wright 1975).

The precise meaning of "attribute importance" as a hypothetical construct is an issue that has been hotly debated, but not fully resolved by consumer researchers (Cohen, Fishbein, and Ahtola 1972; Fishbein 1976; Myers and Alpert 1977; Olson, Kanwar, and Muderrisoglu 1979; Ryan and Holbrook 1979). One clear consensus, however, is that perceived

importance must be distinguished from such related constructs as salience, determinance, and value-satisfaction or evaluative aspect. For the present purposes, the term "attribute importance" will be defined, in the sense suggested by Myers and Alpert (1977), as an attribute's "consequence or significance in making choices among brands or in forming overall evaluations or rankings of products" (p. 106).

When attribute importance is thus defined, its hypothesized role in directing information acquisition receives indirect support from several theoretical perspectives. It is reasonable, for example, to assume that an attribute's perceived importance will depend upon the range in relative magnitudes of the payoffs associated with its different possible levels. When uncertainty characterizes such outcomes, Bayesian decision theory suggests that search in problem solving will depend in part upon this degree of discrepancy among conditional payoffs (Edwards 1965). Similarly, Berlyne's (1960) theory of cognitive motivation relates the receiver's degree of exploratory behavior to the strength or "importance" (p. 36) of the competing response tendencies aroused by a cue. Such competing response tendencies (e.g., approach versus avoidance) engender conflict, which is relieved by specific exploration of the stimulus array. The stronger or more important the response tendencies, the more extensive the resulting specific exploration. An analogous concept in consumer research is the conflict that occurs when the consumer feels low self-confidence in choosing between alternatives with potentially serious consequences. The theory of perceived risk (Cox 1967) argues that, where such uncertain choices involve "important" consequences, increased search for information is one possible coping strategy for reducing the resulting level of risk back down to a tolerable level.

Such propositions from Bayesian, Berlynean, and perceived-risk theory have typically been applied by consumer researchers at the brand or product-class level. Nevertheless, they may reasonably be expected to pertain with equal force to the acquisition of information about a brand's attributes. Such an hypothesized relation between attribute importance and search priority was first tested by Tigert (1966) and has since received increased empirical support in several more recent studies (Heeler, Okechuku, and Reid 1979; Holbrook and Maier 1978; Sheluga, Jaccard, and Jacoby 1979; Quelch 1978). Indeed, decision-net researchers have sometimes actually defined attribute importance as the adjusted average rank of an attribute in the sequence of information seeking (Bettman 1974; Jacoby, Chestnut, Weigel, and Fisher 1976; Nakanishi and Bettman 1974).

Importance and Attitude Structure

Numerous studies have documented the failure of attribute-importance weights to improve upon the predictive performance of summative multiattribute attitude models (for reviews, see Bass and Wilkie 1973; Cohen, Fishbein, and Ahtola 1972; Lutz and Bettman 1977). A second implication of the Principle of Parsimony, however, is that attribute importance might plausibly play another kind of role in multiattribute models by serving as the basis for a parsimonious information-processing heuristic in which cues are combined in a relatively simple, energy-conserving way

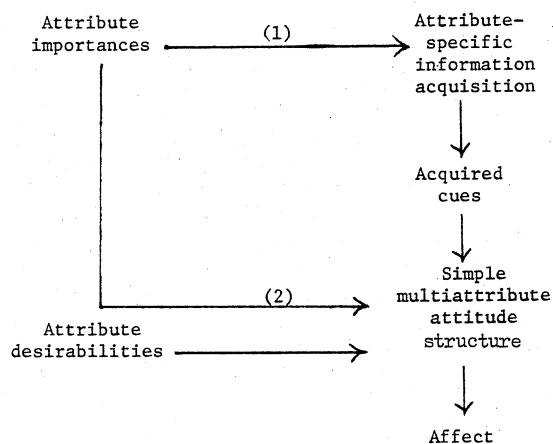

by restricting attention to a small set of most-important attributes. In this light, many studies have shown that a very simple model of attitude structure, summing only the scores on those attributes considered the few most important, predicts affect at least as well as more complex weighted forms of the multiattribute model (Bass and Wilkie 1973; Holbrook 1978; Holbrook and Hulbert 1975; Nakanishi and Bettman 1974; Wilkie, McCann, and Reibstein 1973). Attribute importance therefore appears to serve not so much as a weight in a complex multiattribute model, but rather as a factor directing the simplification of attitude structure.

An Integrative Model

The foregoing considerations may be summarized by the integrative model of importance-directed information processing shown in Figure 1.

FIGURE 1

A MODEL OF IMPORTANCE-DIRECTED INFORMATION PROCESSING

This model emphasizes the proposed role of attribute importance in linking information acquisition with attitude structure. According to Arrow (1), when confronted with the need to evaluate unfamiliar versions of some established product, the decision maker should seek information on those attributes viewed as most important. Arrow (2) then indicates that the perceived desirability values of the limited set of cues thus acquired should serve as the basis for appraising competing versions. Thus, the much-publicized debate concerning the role of attribute importance (e.g., Bass and Wilkie 1973) is resolved by a dynamic model hypothesizing that importance guides the acquisition of information that, in turn, determines the structure of attitude.

As indicated earlier, some empirical support already exists for the hypothesized relationships represented by Arrows (1) and (2). However, with few exceptions (e.g., Holbrook and Maier 1978; Sheluga et al. 1979), such support appears to be largely piecemeal in nature--focusing on one relationship or the other, but not on both at the same time. Thus, there is little firm evidence for the simultaneous operation of both arrows as part of a dynamic process in which importance guides the acquisition of cues that then compose the structure of attitude. Therefore, because this plausible, but inadequately tested integrative hypothesis appears to provide a useful way of linking research on information acquisition with that on attitude structure, the chief purpose of the present study was to provide a clearly-focused test of the importance-directed

model of information processing.

Methods for Studying Information Acquisition

Methods for studying the acquisition of information have recently been the topic for extended reviews, comparisons, and evaluations (Arch, Bettman and Kakkar 1978; Bettman 1977; Chestnut and Jacoby 1978; Jacoby, Chestnut, Hoyer, Sheluga and Donahue 1978; Payne and Ragsdale 1978; Russo 1978). Briefly, the most frequently advocated approaches for investigating search processes involve the use of: (1) eye-fixation tracking, in which mechanical instrumentation monitors the eye movements of subjects scanning some visual field; (2) verbal protocols, in which the subject provides a running account of his conscious thought processes while performing a decision task; or (3) information-display boards, in which the subject selects cards containing information from a multi-celled brands-by-attributes matrix.

One seldom-mentioned limitation of most such approaches is their implicit restriction to the confines of a laboratory or other closely monitored setting in which individual sessions are conducted with what, for cost reasons, usually turns out to be a small convenience sample. Given the need for marketing research on large, representative samples of consumers (Ferber 1977a), the standard repertoire of techniques for studying information acquisition may prove inadequate to the task of obtaining generalizable results. Toward this end, Holbrook and Maier (1978) introduced a modification of the information-display board intended to be usable in a mail questionnaire and, therefore, suitable for inclusion in studies employing large-scale survey techniques. Briefly, this procedure presents the respondent with a brands-by-attributes information-display sheet in which each cell is covered by a numbered sticker. The respondent acquires information by peeling stickers from the matrix and replaces them at the bottom of the page in a manner that provides a permanent record of the order in which they were removed. Holbrook and Maier (1978) found that this task was easily understood and performed by student subjects. A subsidiary purpose of the present study was to provide a further test of the usefulness of this questionnaire-based information-acquisition task.

Previous Findings Concerning the Importance-Directed Information-Processing Model

The Holbrook-Maier study. Using the sticker-pulling task in a study simulating the evaluation of phonograph records, Holbrook and Maier (1978) found evidence consistent with the importance-directed information-processing model. Across six attributes, there were highly significant mean intra-individual correlations between rated attribute importance and (1) number of cues selected on that attribute ($\bar{r} = .59, p < .0001$) and (2) average sequential order of selecting cues on that attribute ($\bar{r} = .63, p < .0001$). Using desirability ratings of the acquired cues in multi-attribute models to predict preference produced equally good intra-individual rank-order correlations whether additive ($\bar{r} = .57$ and $.56, p < .0001$) or averaging ($\bar{r} = .54$ and $.55, p < .0001$) models were employed. This finding was interpreted as exploratory evidence bearing on the debate between adding versus averaging formulations (Anderson 1967, 1976; Bettman, Capon and Lutz 1975; Fishbein 1976; Fishbein and Ajzen 1975; Lutz 1976; Troutman and Shanteau 1976). Apparently, when selective information acquisition is permitted rather than forcing exposure to factorially-designed stimuli, averaging models may not enjoy any predictive superiority over additive versions.

The Quelch study. Quelch (1978) produced support for the first Holbrook-Maier finding by asking housewives to choose among six brands of cold cereal after acquiring information on either four or five attributes. The mean intra-individual rank-order correlation between the order of information selection and a subsequent measure of attribute

The Høler study. Høler, Okechuku, and Reid (1979) contributed further support for the first Holbrook-Maier finding. Two groups of student subjects provided importance ratings or display-board search measures for 10 attributes of electric blenders. Rank-order correlation of aggregate scores across attributes found a moderately strong relationship between average rated importance and mean frequency of acquisition: $\bar{r} = .53$ ($p < .10$).

The Sheluga study. Finally, in a study performed concurrently with that reported in the present paper, Sheluga, Jaccard, and Jacoby (1979) extended Holbrook and Maier's (1978) "integrative approach" to include a comparison of several competing scaling methods. Though several of their findings concerning the evaluation of cameras are of considerable interest in their own right, the two most relevant to the issues addressed here are: (1) significant average Spearman correlations between retrospective "search importance" and extent ($\bar{r} = .80$, $p < .001$) and order ($\bar{r} = .68$, $p < .001$) of attribute-specific information acquisition; (2) relatively strong choice predictions (percentage correct) based upon acquired cues scored for utility by rating scales (64%), conjoint measurement (70%), and graded paired comparisons (100%).

Limitations in the Previous Findings

One limitation in Holbrook and Maier's (1978) design was the fact that questionnaires were distributed by hand, thus raising questions concerning the usefulness of the sticker-pulling technique in mail-survey research. A subsidiary objective of the present study, therefore, was to establish the feasibility of this method for use in surveys that are distributed through the postal system.

A second weakness in the Holbrook-Maier study raised a possible alternative hypothesis to explain their finding concerning the effect of attribute importance on search direction. Specifically, attributes were inadvertently arrayed on the information-display sheet from left to right roughly in order of their overall average perceived importance. In accord with the well-established effect of task format on performance in information-acquisition strategies (Bettman and Kakkar 1977), it might therefore be argued that the relationship between attribute importance and cue selection could have resulted from respondents' tendencies to move from left to right in searching for information (Quelch 1978). Accordingly, another subsidiary objective of the present study was to rule out this alternative explanation by randomly rotating the order of the attribute columns in the information-display sheet.

A further limitation in the Holbrook-Maier design raised doubts concerning the apparent equality of predictive performance by additive and averaging attitude models. Since respondents selected information by self-exposure, it is possible that they tended to acquire the same number of cues for each stimulus object. Such a naturally-occurring lack of variation in the extent of search among objects could account for the absence of predictive differences between additive and averaging models since the two kinds of formulation give identical results when the number of cues processed on each stimulus is constant (Anderson 1967; Fishbein and Ajzen 1975). The present study therefore attempted, as a third subsidiary objective, to encourage variation in the number of cues chosen on various stimulus objects by constraining the respondent to choose exactly 24 cues in evaluating 8 objects. Thus, if a number of cues other than three were chosen on any one stimulus, some variation in cue utilization among objects would be insured.

To maintain comparability with previous research using the sticker-pulling task, phonograph records were chosen as the product category to be tested. In accord with a suggestion by Ferber (1977b), the sample was composed of first year MBA students who demonstrated an interest in this product class by virtue of having purchased at least two pop or jazz recordings within the past six months. Questionnaires were mailed to 136 potential respondents, of whom 101 returned complete and usable sets of data for a response rate of 74%.

Evaluation Task

Respondents were asked to evaluate eight vocal recordings that differed on six alphabetically-listed attributes. Each attribute was defined by the following set of dichotomous characteristics: (1) Jacket--informative or visual; (2) Label--major or independent; (3) Singer's Style--traditional or contemporary; (4) Type of Music--pop or jazz; (5) Type of Production--studio or live; (6) Type of Songs--standards or originals and recent hits. These 6 attributes and 12 defining characteristics were described on the introductory page of the questionnaire by short paragraphs (omitted here for brevity) and were identical to those used by Holbrook and Maier (1978), except that Price in their study was replaced by Type of Music to avoid the somewhat ambiguous implications of price for preference formation.

Attribute-Specific Measures of Importance and Desirability

The six attributes were rated on 7-point check-mark scales for their degree of importance to the respondent's evaluation of a vocal recording from "not at all important" to "extremely important." In addition, the 12 defining characteristics were rated on comparable scales for their desirability in a vocal album from "extremely undesirable" to "extremely desirable." Importance ratings were scored from 1 to 7 while, in acknowledgement of the debate surrounding the proper coding of evaluative scores (Fishbein 1976; Holbrook 1977; Lutz 1976), two alternative codings of the desirability ratings were investigated: -3 to +3 and 1 to 7.

Test Objects

The dichotomous characteristics for each attribute were used to specify eight vocal albums according to the kind of fractional factorial design described by Green (1974) as suitable for conjoint measurement studies. The rows of the resulting 8 x 6 matrix were randomized and labelled from "Record A" to "Record H." To guard against the possibility of any position effects on the extent or order of cue acquisition (Bettman and Kakkar 1977; Quelch 1978), the columns of this basic information matrix were then arranged into 10 different random sequences. These 10 sequences were, in turn, assigned randomly to respondents.

The Information-Acquisition Task

As a basis for evaluating the vocal albums, the questionnaire provided an information-display sheet consisting of one of the 10 randomly-arrayed matrices with each cell covered by an appropriately labelled gummed sticker. The respondent was instructed to remove the 24 stickers that would best provide the information needed to rank the eight records in order of preference. Further instructions asked the respondent to replace each sticker, in its order of removal, into another matrix entitled "Order of Sticker Removal" with cells labelled from "1st" to "24th." Following this task, the respondent ranked the eight recordings in order of preference.

Operational Definitions

Extent and order of attribute-specific information acquisition. The extent of attribute-specific information acquisition was defined operationally as the number of cues acquired across all eight records on that attribute. The order of acquisition was defined as the average rank of selecting information on that attribute across the eight records (with the rank order for non-acquired cues scored arbitrarily as 36.5—i.e., half way between 25th and 48th.)

Models of attitude structure. The full set of competing attitude-structure models developed by Holbrook and Maier (1978) was tested in the present study. Specifically, the comparative predictive performance of additive and averaging models was explored, both with and without importance weights and with desirability scored both from -3 to +3 and from 1 to 7. In accord with the previous findings, however, no discernible differences arose from the inclusion of importance weights or from the alternative scorings of desirability. To save space, the present discussion will therefore be confined to the most conceptually appropriate attitude models—namely, those without importance weights and with desirability scored from -3 to +3 (Fishbein 1976; Fishbein and Ajzen 1975; cf. Rosenberg 1956). With this restriction, the competing models investigated may be represented as follows:

$$\text{Partial Additive Model} = \sum_{k=1}^6 B_k \cdot E_k \cdot ACQ_k \quad (1)$$

$$\text{Partial Averaging Model} = \left(\sum_{k=1}^6 B_k \cdot E_k \cdot ACQ_k \right) / \left(\sum_{k=1}^6 ACQ_k \right) \quad (2)$$

$$\text{Full Additive Model} = \sum_{k=1}^{12} B_k \cdot E_k \cdot ACQ_k \quad (3)$$

$$\text{Full Averaging Model} = \left(\sum_{k=1}^{12} B_k \cdot E_k \cdot ACQ_k \right) / \left(\sum_{k=1}^{12} ACQ_k \right) \quad (4)$$

where k refers to the 12 characteristics that a given record does ($k = 1, \dots, 6$) and does not ($k = 7, \dots, 12$) possess; $B_k = 1$ if the record possesses characteristic k or $B_k = -1$ if it does not; E_k is the respondent's evaluation of the desirability of characteristic k ; and ACQ_k is a zero-one dummy variable representing the acquisition of information on characteristic k .

More colloquially, the Partial Additive Model may be described as the summed desirability scores of those characteristics known, after search, to be present in a given record album (where it is assumed that the respondent believes the information he has received to be true). The Partial Averaging Model is the mean desirability of those known characteristics. The Full Additive Model further subtracts the desirabilities of those characteristics revealed to be absent from a given recording (on the assumption that the respondent makes inferences about what characteristics are missing from the record). And the Full Averaging Model computes the mean desirability of the present characteristics less that of those absent.

The full models assume that preference may be enhanced (reduced) by the absence of undesirable (desirable) characteristics, thereby incorporating logic analogous to that arguing for the bipolar coding of components in the Fishbein model (Fishbein 1976; Fishbein and Ajzen 1975; cf. Rosenberg 1956). Even these fuller versions of the attitude model do not, of course, account for the effects of additional beliefs that may be inferred on the basis of the information that has been acquired (Fishbein and Ajzen 1975; Lutz and Swasy 1977; Olson 1978). This, of

course, is a limitation that is shared by the vast preponderance of attitude research.

In comparing the additive and averaging models, it is important to recognize that any differences between them in the present design result from the fact that respondents are free to select different numbers of cues for different vocal albums. Where the variation among records in the extent of acquisition is relatively large, the two types of formulation may make substantially different preference-rank predictions. The degree of such differences is an empirical issue, however, and not part of the research design controlled by the investigators themselves. Thus, this part of the study is correlational rather than experimental in nature.

Operational Hypotheses

Given the arguments and findings reviewed earlier, four specific hypotheses were tested:

- H₁. Extent and order of attribute-specific information acquisition are positively related to attribute importance on an intra-individual basis;
- H₂. Attitude-structure models based on the cues acquired predict intra-individual preference ranks;
- H₃. The partial attitude models perform at least as well as the full models in predicting preference ranks;
- H₄. The predictive performance of additive attitude models is at least as good as that of averaging models.

Results

In accord with the findings of Holbrook and Maier (1978), respondents appeared to experience few problems with the self-administration of the mail questionnaire. Only three questionnaires had to be discarded because of failures to follow the written instructions. The likely effect of such difficulties on the results obtained in an information-acquisition task therefore appears to be minimal.

H₁. The first hypothesis was supported by highly significant mean intra-individual correlations of attribute importance with (1) extent of information acquisition ($\bar{r} = .665$, $Z_{\bar{r}} = 21.08$, $p < .0001$) and (2) order of information acquisition ($\bar{r} = .674$, $Z_{\bar{r}} = 22.81$, $p < .0001$).

Because of the presence of a small number of low-correlation outliers, the median intra-individual correlations were considerably stronger than the means: .775 and .782 respectively. These results compare favorably with the previously cited findings.

H₂. The results for all four versions of the attitude-structure model supported the second hypothesis by performing fairly well in predicting preference rank, with mean intra-individual rank-order correlations as follows: Partial Additive Model— $\bar{r} = .642$ ($Z = 19.63$, $p < .0001$); Partial Averaging Model— $\bar{r} = .602$ ($Z = 16.91$, $p < .0001$); Full Additive Model— $\bar{r} = .598$ ($Z = 7.73$, $p < .0001$); Full Averaging Model— $\bar{r} = .597$ ($Z = 16.86$, $p < .0001$). Because of skewed distributions, the median correlations were again somewhat stronger than the means, ranging from .673 to .756. These relationships were, if anything, somewhat better than those found by Holbrook and Maier.

H₃. In further accord with the Holbrook-Maier results, the third hypothesis was supported by the failure of either full attitude-structure model to perform better than its corresponding partial version. This finding contradicts the assertion that affect is determined, in part, by the

evaluative aspects of those characteristics that are believed to be missing from some object.

H_4 . Finally, in line with previous findings and the fourth hypothesis, neither averaging model improved upon the predictive performance of its additive counterpart. It appears, however, that constraining respondents to the selection of 24 pieces of information was only moderately successful in encouraging variation in the number of attribute cues acquired across stimulus objects. Thus, 49 out of 101 respondents showed no variation in the number of cues selected across recordings. As pointed out earlier, for such respondents, additive and averaging attitude models make identical preference predictions. The removal of these 49 respondents from the sample would only result, however, in an even greater relative superiority in the predictive performance of the Partial Additive Model versus the Partial Averaging Model ($\bar{r} = .622$ versus $.542$). Such a procedure, therefore, would not change the basic conclusion that averaging models do not improve upon the predictive performance of additive versions. Accordingly, the more conservative comparison, based on the full sample of 101 respondents, should be used in summarizing the results for H_3 and H_4 .

In this light, the findings concerning H_3 and H_4 may be summarized by comparing the predictive performance of the Partial Additive Model with that of the other three versions. In each case, the Partial Additive Model performed slightly, but significantly better in predicting preference: $\bar{r} = .642$ versus $.602$ ($t_{100} = 3.09$, $p < .01$); $\bar{r} = .642$ versus $.598$ ($t_{100} = 3.02$, $p < .01$); and $\bar{r} = .642$ versus $.597$ ($t_{100} = 2.89$, $p < .01$). It therefore appears that, in the kind of information-acquisition task investigated here, the Partial Additive Model is to be preferred over the full and/or averaging versions--partly because of its marginal predictive superiority, but primarily because of its greater parsimony.

Discussion

Limitations

Like most presently available research on attitude formation or information acquisition, the present study is characterized by certain limitations. The attitude model, for example, required the plausible, but untested assumption that the respondents believed the information to which they were exposed and, in effect, assigned each cue a subjective likelihood of 1.0. Also, the model could not account for the effects of any additional beliefs that might have been inferred on the basis of the cues acquired (Fishbein and Ajzen 1975; Lutz and Swasy 1977; Olson 1978). In these respects, however, the present approach shares assumptions that are fundamental to the vast preponderance of attitude research, including most of the work on conjoint analysis and information integration. Moreover, the importance of inferential beliefs in this study is called into question by the absence of any predictive improvement to be gained by including characteristics implicitly revealed to be absent from the recording (i.e., $E_k = -1$).

In common with other information-acquisition paradigms (eye-fixation tracking, display boards, protocols, etc.), the present search task was highly artificial in many respects. Restricting respondents to the use of 24 cues, for example, was one way of setting a reasonable limit on the amount of information acquired so as to permit some variance in cue utilization across attributes. Other methods for limiting cue selection--such as charging five cents per cue--would have been less practical in a mail questionnaire. Moreover, it appears doubtful whether any one way of restricting information intake is inherently more realistic than another.

In contrast to many applications of the information-display board, the cues uncovered by respondents in the present study remained visible and did not, therefore, place any demands on memory capacity. The authors would argue that this procedure has the advantage of removing the confounding effects of memory overload, but some might feel that this constitutes a departure from realism.

Further, the recordings employed in the present study were hypothetical rather than real, though respondents were not informed of the fictitious nature. The advantage of using such artificial products is that it permits an otherwise unattainable degree of experimental control. Accordingly, this kind of artificiality appears in numerous other studies of information processing--including many of those on cognitive algebra (e.g., Bettman, Capon, and Lutz 1975), conjoint measurement (e.g., Green 1974), and attitude change (e.g., Lutz 1975).

Finally, it should be noted that--though the approach used here is of some use in comparing the predictive efficacy of simple additive versus averaging models (Fishbein and Ajzen 1975)--it cannot discriminate between an additive model and the more elaborate weighted averaging model proposed by Anderson (1967) to take account of the "set size" effect. This latter formulation assumes that affect begins at an initial value that is then adjusted by the averaging-in of subsequent information. Such a model produces predictions that are quite similar to those generated by a simple additive representation. As pointed out by Fishbein and Ajzen (1975, p. 242), the inability to distinguish between a simple additive model and Anderson's (1967) differentially weighted averaging version is a limitation shared by most of the research in this area.

Conclusions

Subject to such limitations, the present study supports the proposed model of importance-directed information processing. Specifically, its results suggest (1) that attribute importance guides the acquisition of attribute-related cues and (2) that these cues are then incorporated into a relatively simple importance-shaped attitude structure so as to determine affect. Though both these effects have been supported independently by earlier studies, previous research has tended not to treat them together as parts of one dynamic importance-directed process. The present findings therefore suggest the usefulness of research attempting to integrate information-acquisition phenomena with the nature of multiattribute attitude structure.

In addition, the present study continues to support the adequacy of the relatively parsimonious Partial Additive Model when compared with more elaborate competing versions. To be sure, the research design left the respondent free to select among the six cues available for each object instead of being exposed to factorially-arranged combinations of cues so that the comparative tests of predictive performance are correlational rather than experimental in nature. Moreover, like most other research on consumer attitudes, the present study failed to account for the effects of additional beliefs that might be inferred from those explicitly manipulated and/or measured. Nevertheless, within this restricted framework, the findings may further reinforce the doubts of those questioning the often-claimed superiority of the averaging model (Fishbein 1976; Fishbein and Ajzen 1975; cf. Anderson 1967, 1976; Bettman, Capon, and Lutz 1975; Lutz 1976; Troutman and Shanteau 1976).

Finally, the study confirms the feasibility of the sticker-removal task as a device for incorporating the information-acquisition paradigm into mail-survey research designs. Though the respondents in the present study were students, the authors would anticipate no difficulties in applying the technique in mail questionnaires directed at larger scale, more representative samples. Obviously, the external

validity of such an approach remains to be tested. But, on the basis of the evidence presented here, it appears that the label-pulling task may be useful in future attempts to generalize findings concerning information acquisition to the overall consumer population.

EXAMINING THE DIAGNOSTIC UTILITY OF THE
FISHBEIN BEHAVIORAL INTENTIONS MODEL¹

Paul W. Miniard, The Ohio State University

Abstract

Evidence and issues relevant to the diagnostic utility of the Fishbein Behavioral Intentions model are discussed. Two experiments are then presented that examine the degree to which the weight associated with the normative component of the model can accurately reflect the absence or presence of salient normative influences.

Introduction

One promising approach to understanding the important motivations underlying a given behavior is represented by the Fishbein Behavioral Intentions (FBI) model. On the basis of a predictive criterion, the model's performance has been substantiated for a variety of behavioral objects such as alcohol (Schlegel, Crawford, and Sanborn 1977), birth control pills (Davidson and Jaccard 1975), female occupations (Greenstein, Miller, and Weldon 1979), financial loans (Ryan and Bonfield 1980), marijuana (Bearden and Woodside 1978), swine flue vaccinations (Oliver and Berger 1979), and toothpaste (Wilson, Mathews, and Harvey 1975). However, the prediction of intention alone offers little pragmatic value. Rather, the promise of any such formulation lies in its potential for generating information that is useful in developing behavioral change strategies. But before the model can be confidently employed for diagnostic purposes, attention should be directed at examining the model's diagnostic utility; that is, the extent to which the model leads to correct inferences about the determinants of intention and behavior. It is to this issue that this paper addresses itself. After briefly reviewing the FBI formulation, discussion turns to the possible threats to the model's diagnostic utility. Two experiments are then presented that examine the model's diagnostic accuracy under conditions that differ in the salience of normative influence.

The Fishbein Behavioral Intentions Model

The FBI model postulates that intention, viewed as the immediate antecedent of behavior, is determined by an attitudinal or personal component and a normative or social component (Fishbein and Ajzen 1975):

$$B \sim BI = w_1 (A_B) + w_2 (SN), \quad (1)$$

where B is the behavior, BI is the behavioral intention to perform behavior B; A_B is the attitude toward performing behavior B; SN is the subjective norm; and w_1 and w_2 are empirically determined weights.

The first component, A_B , is the person's attitude toward performing a particular behavior under a given set of circumstances. This attitudinal component can be decomposed into the perceived consequences of performing the behavior weighted by the evaluation of these consequences:

$$A_B = \sum_{i=1}^n b_i e_i, \quad (2)$$

where b is the belief that performing behavior B leads to consequence i; e is the person's evaluation of consequence i; and n is the number of salient beliefs.

The second component, SN, represents the person's perception of what important others think s/he should do which is proposed to be a function of the person's beliefs about the expectations of important referent others, and her/his motivation to comply with these referents:

$$SN = \sum_{j=1}^n NB_j MC_j \quad (3)$$

where NB is the normative belief (i.e., the person's belief that reference group or individual j thinks s/he should or should not perform the behavior); MC is the person's motivation to comply with referent j; and n is the number of relevant referents.

The importance of these two components in determining intentions is expected to vary with the behavior, the situation, and individual differences between persons. Some individuals, for example, may be more "sensitive" to social demands and therefore may attach more weight to their normative considerations than other individuals. Similarly, behaviors that carry greater interpersonal significance or that are visible to important others may be more susceptible to social influences than behaviors that have less interpersonal implications or that are less observable. The component weights (i.e., w_1 and w_2), which are traditionally estimated by multiple regression procedures, presumably reflect both the existence and the relative importance of these two determinants.

Criteria for Establishing the Model's Diagnostic Utility

Before any model that attempts to identify the determinants of behavioral intention can be confidently employed for diagnostic purposes, there are several important criteria that the model should meet. First, a model that decomposes the determinants of intention is useful only to the extent that there exists a strong relationship between intentions and behavior. Second, the causal flow hypothesized by the model should be validated. Third, the model should be fully identified in the sense that exogeneous variables (i.e., variables other than those postulated by the model as the immediate antecedents of intention) will affect intentions only indirectly (i.e., the exogeneous variable's influence on intention is mediated by one or more of the postulated determinants). Fourth, the weights employed for representing the presence and relative importance of the hypothesized determinants of intention should accurately reflect "reality". Each of these criteria are in turn discussed below with a brief review of the research relevant to each.

The Intention-Behavior Relationship

One major assumption of the FBI model is that "behavioral intentions are the immediate determinants of the corresponding overt behaviors" (Fishbein and Ajzen 1975, p. 372). If behaviors are not predictable from intentions, there

¹Appreciation is extended to Joel B. Cohen for his assistance in the development of the experiments presented in this paper.

would be little value in specifying and validating a model that identifies the determinants of intentions. Thus, establishing the existence of an intention-behavior relationship as well as the factors that influence the magnitude of this relationship is of crucial importance.

Much of the work relevant to this issue is reviewed by Fishbein and Ajzen (1975, pp. 372-381) and thus need not be repeated here. In general, the assumption of an intention-behavior relationship has been supported, although Fishbein and Ajzen (1975, pp. 368-372) do point out that this relationship is dependent upon (1) the degree to which the measure of intention corresponds directly to the observed behavior, (2) the time interval between measurement of intention and the behavior's occurrence, and (3) the degree to which the person is able to act in accordance with his intention or without the assistance of others. A strong relationship between intention and behavior is expected when the intention measure is specific to the behavior of interest, performance of the behavior is temporally close to the measurement of intention, and the behavior is under volitional control.

Verifying the Hypothesized Causal Flow

As implied by Equations 1, 2, and 3, the FBI model postulates that (1) the influence of A_B and SN upon B are mediated by BI, (2) the influence of Σb_{ie_j} upon BI is mediated by A_B , and (3) the influence of $\Sigma NB_j MC_j$ upon BI is mediated by SN. For the most part, this hypothesized causal flow has been substantiated. In an examination of BI's mediating role, Ajzen and Fishbein (1970) held BI constant and tested the partials between B- A_B and B-NB. This procedure completely eliminated the previously significant B-NB relationship. The B- A_B partial correlation was significant, however, in only one of the two statistical tests. Similarly, Ryan and Bonfield (1980) found that initially significant B- Σb_{ie_j} and B- $\Sigma NB_j MC_j$ relationships became insignificant when BI was partialled out. Further support is provided by Ajzen and Fishbein (1974) where changes in BI were related to changes in A_B and $\Sigma NB_j MC_j$. In a product evaluation setting, Lutz (1977) tested the causal relationships assumed by the FBI model and concluded that the results provided "reasonably strong support for the postulated flow of effects" (p. 206), although several conceptual and methodological concerns regarding the study and the conclusions drawn have been raised (cf. Carnegie-Mellon University Marketing Seminar 1978; Dickson and Miniard 1978; Lutz 1978a,b).

Several investigations have failed to support the postulated causal flow. Miniard and Cohen (1981) found that, contrary to the causal flow involving the normative component, the addition of $\Sigma NB_j MC_j$ into a regression model containing SN provided a significant improvement in the prediction of BI. This finding casts doubt upon SN's ability to mediate the effects of $\Sigma NB_j MC_j$ upon BI. Further, Bentler and Speckart (1979) report that attitudes and past behavior accounted for a significant portion of behavior that was not mediated by intention.

The Model's Mediation Adequacy

One assumption underlying the model that has received considerable attention is that exogeneous variables will affect intentions only indirectly through either component of the model. Thus, any variable related to intentions should also be related to one of the model's components. Further, any relationship between such variables and intentions should be eliminated when A_B and SN are statistically held constant (e.g., the addition of an external variable should not provide a significant increment in the prediction of intentions).

Several approaches have been adopted for operationalizing these external variables. Survey-based investigations have examined the model's ability to mediate such

exogeneous variables as religion, age, occupational prestige, and assorted personality and social constructs. In an early study involving transplant donations, Schwartz and Tessler (1972) found a subset of these external variables increased the model's ability to predict intentions. Later investigations, however, have supported the model's mediational adequacy. Jaccard and Davidson (1975) concluded from their study of family planning that the addition of external variables did not provide substantive predictive improvements. Similarly, in the realm of adolescent alcohol use, Schlegel, Crawford, and Sanborn (1977) stated that "...present results could hardly be considered to provide a psychologically meaningful basis for any revision of the Fishbein theory" (p. 428). Attention has also been directed at the components' ability to mediate the effects of the traditionally employed attitude toward an object (A_0) upon intentions. Several investigations have shown that A_0 is mediated by the model's components (Ajzen 1971; Ajzen and Fishbein 1970, 1974) although others have found the components unable to completely mediate A_0 (Jaccard and Davidson 1975; Schwartz and Tessler 1972).

An alternative approach to this issue has been to examine the extent to which the components mediate the effects of assorted experimental manipulations upon intentions. Ajzen and Fishbein (1970) report that while holding A_B and NB constant strongly attenuated the effects of the two experimental manipulations upon intentions, one of the manipulations still remained significant. This latter finding was replicated by Songer-Nocks (1976b), although this and related findings have been debated (Fishbein and Ajzen 1976a,b; Songer-Nocks 1976a). Unconditional support for the components' ability to mediate the effects of experimental manipulations upon intentions is provided by Ryan (1977).

To summarize, evidence bearing on the model's mediational adequacy has been mixed, with some investigations supporting the model's ability to mediate exogeneous variables while other research has shed a less favorable light. However, even in those cases where the components have not completely mediated the effects of external variables, they have greatly attenuated the relationship between such variables and intentions.

Validity of the Component Weights

One key validity concern is the model's accuracy in identifying both the existence and relative importance of salient attitudinal and normative influences. If attitudinal and normative influences were equally important in determining intentions, one would hope that the component weights would correctly represent this condition. One should also expect a given determinant to receive a significant weight when the determinant is in fact important in guiding intentions and not to receive a significant weight when it does not influence intentions. If this were not the case, then the diagnostic usefulness of the model would be limited.

Several factors could threaten the validity of the component weights and thus the model's diagnosticity. Multicollinearity between the components, for instance, can lead to situations where salient influences receive an insignificant weight while a significant weight is assigned to nonsalient influences (this latter situation has been discussed by Cohen and Cohen 1975 under the label of suppressor variables). Reason to suspect the model on this basis has been provided by Miniard and Cohen (1979) as they found the attitudinal and normative measures currently used for model implementation to be inadequate in separating these two sources of influence. The weights' accuracy should also be dependent on the measures' ability to fully capture the causal influences that affect intentions. It has recently been shown that SN may not mediate the influence of MC upon intentions (Miniard and Cohen 1981). This implies

that the normative component may be less accurate when SN is used for measuring normative influences.

Evidence demonstrating that the measures are not distinct or that they fail to fully mediate influences which they should capture, however, is limited in that it only establishes the potential for inaccurate weights. It may be that, even in the presence of such problems, the weights correctly reflect the salient influences. What is needed, then, is a direct test of the weights' validity.

Two possible criteria for evaluating the validity of the component weights are (1) the weights' ability to represent the absence or presence of salient attitudinal and normative influences and (2) whether the weights differ in their relative sizes in expected ways. Under the first criterion, the normative weight, for example, should be significant when normative influences are important determinants of intentions. Similarly, the weight should not be significant when normative influences are unimportant. Failure to confirm these expectations would cast serious doubt upon the model's diagnostic usefulness. The second criterion is less concerned with the accuracy of a particular weight. Rather, the focus is on the relative magnitude of the weights. Drawing upon some conceptual framework, one might hypothesize that a given component should be more important (i.e., have a larger weight) in situation A with the remaining component dominating intentions in situation B. Note that support for one criterion does not automatically imply support for the other. For instance, one might be led to predict that both sources of influence are important (Criterion 1), although the attitudinal component should be more important than the normative component (Criterion 2). If the results yielded a large significant attitudinal weight but a small insignificant normative weight, only the latter prediction would be supported.

Research examining the weights' validity has, without exception, relied upon the second criterion. Using the Prisoner's Dilemma game, Ajzen (1971) and Ajzen and Fishbein (1970) told subjects to consider themselves partners (cooperation condition) or to do better than the other person (competitive condition). It was expected that normative considerations would carry greater weight in the cooperation condition while attitudinal considerations would be more important in the competitive condition. The observed patterns of regression weights supported these predictions. Similar results derived from this experimental paradigm are reported by Songer-Nocks (1976b).

Wilson, Mathews, and Monoky (1972) found partial support for hypothesized differences in the weights' relative magnitudes. As predicted, the attitudinal component received a larger weight when the other person in a buyer-seller dyad was described as being dissimilar to the subject. The attitudinal component was also dominant when the other was described as being similar, although it was expected that the normative component would be of greater importance.

Evidence failing to support expected differences in the components' relative weights within a marketing context is reported by Ryan (1978). When the model was applied to two brands of toothpaste, social influences were predicted to be more important for Ultra Brite than Crest since the former's promotional activities emphasized social interactions. The results contradicted this hypothesis as the normative weight was larger than the attitudinal weight for Crest while the reverse was true for Ultra Brite.

As stated above, evidence addressing the weights' accuracy in representing the presence or absence of salient normative and attitudinal influences is nonexistent. However, close inspection of the correlational and regression analyses reported in several investigations suggests that the weights may not be accurately reflecting the true importance of a given component. In particular, it is often the case that a component correlates significantly with

intentions yet receives an insignificant weight. Fishbein (1966), for example, reported that males' attitude toward premarital sexual intercourse had a significant correlation with their intention to engage in this behavior but received an insignificant weight in the regression equation. The same result with respect to $\Sigma NB_j MC_j$ is reported by Ajzen and Fishbein (1972) where the normative component weight was insignificant although $\Sigma NB_j MC_j$ was significantly correlated with intentions. An extreme instance of these inconsistencies where actual behavior was the criterion is provided by Ajzen and Fishbein (1970). As reported in Table 4 of their results, both A_j and NB were significantly related to behavior but neither measure received a significant regression weight. Further examples of significant correlations and insignificant weights can be found in Greenstein, Miller, and Weldon (1979), Schwartz and Tessler (1972), and Warshaw (1980).

Unfortunately, evidence that a given component receives a significant correlation but an insignificant weight can not be unambiguously interpreted as evidence against the model's diagnostic utility. It may be the case that the measure should not correlate significantly with intentions. If the measure used to operationalize the normative component was sensitive to attitudinal influences (i.e., the normative measure also tapped the attitudinal component), the normative component might correlate with intention even when the intention is solely under attitudinal control. In such situations, the lack of a significant normative weight is quite appropriate. However, if a significant correlation between the normative component and intentions is valid in the sense that normative influences do play an instrumental role in determining intentions, the model's failure to assign a significant weight to the normative component would provide a clear indication of the potential for misleading inference. Without knowing whether a given component is in fact important, one cannot easily reconcile inconsistencies between the correlational and regression analyses.

Therefore, the following two experiments will attempt to provide some initial evidence concerning the FBI model's ability to accurately reflect the absence or presence of salient attitudinal and normative influences. In particular, the validity of the normative component's weight will be examined under conditions where (1) the social environment does not influence intentions (Study I) and (2) social influences do affect intentions (Study II).

Study I

Method

Subjects and Procedures. A total of thirty male and female undergraduate marketing students participated in the experiment. Subjects were informed that they were participating in a study of "new product introductions" and that they would receive a booklet containing two role playing descriptions involving a new product. Both descriptions began by asking subjects to assume that they had participated in a nationwide marketing research study of consumers' reactions to a new product. In one of the descriptions, the subject was portrayed as being very favorable toward purchasing the product (Attitude-Positive). The remaining description stated that the subject was very unfavorable toward buying the product (Attitude-Negative). The order of presentation of these two descriptions was counterbalanced across all subjects.

For a third of the subjects, this attitudinal statement completed the description. This condition (Others' Expectations-Unknown) thus represented a situation that was devoid of information concerning the social environment (e.g., whether others thought the subject should purchase the

product). The remaining subjects, however, received descriptions that contained information concerning the opinions of others. Subjects in the Others' Expectations-Positive condition were informed that most others were very favorably toward the new product and that almost everyone had responded "yes" to the question "Do you think others should buy this product?". Conversely, others were described as being unfavorable toward the product in the Others' Expectations-Negative condition and as answering "no" to the question regarding whether others should purchase the product.

Subjects in these latter two conditions (where others' opinions are known) were then told that: "Of course, what others feel you personally should do here is a matter of no concern to you. Buying or not buying the new product is strictly your own decision." These statements were included in order to create a situation in which the social environment is not an important source of influence. If this is the case (which will be examined below), the question then becomes whether the FBI model can correctly reflect via the normative component weight the unimportance of the social environment.

Measures. Prior to completing the following measures, subjects were instructed how the response scales were to be used (e.g., the meaning of the scale categories). Subjects first responded to a measure of BI via three 7-point bipolar semantic differential scales (likely-unlikely, probable-improbable, possible-impossible). Subjects then indicated their attitude toward the behavior ("For me, buying the new product would be:") on four 7-point bipolar evaluative semantic differential scales (good-bad, foolish-wise, rewarding-punishing, harmful-beneficial). Subjects next responded to the SN measure (i.e., "Most people who are important to me think I should/should not buy the new product") via a 7-point scale ranging from "I should" (+3) to "I should not" (-3).

Results

The results of the 2 (Attitude) X 3 (Others' Expectations) ANOVA conducted on subjects' responses to the BI, AB, and SN measures are presented in Table 1. Verification that social influences were not an important determinant of BI required testing the effect of the Others' Expectations manipulation upon subjects' responses to the BI measure. If the provision of information concerning others' opinions did in fact play an influential role in the formation of subjects' intentions to purchase the product, then the Others' Expectations manipulation should have a significant impact on BI. This manipulation did not attain significance ($p < .22$), although the attitudinal manipulation was highly significant and accounted for 92% of the measure's variation, as calculated by use of Hays' (1963) omega-squared (ω^2) statistic. The lack of a significant normative manipulation indicates that beliefs regarding others' expectations were not an important determinant of subjects' intentions to purchase the product. Accordingly, the normative component as operationalized by SN should not receive a significant weight.

Examination of the normative weight's ability to reflect the nonsalient social influences existing in the Others' Expectations-Positive and Negative conditions involved conducting a regression analysis pooling (i.e., collapsing across the experimental cells after adjusting for differences in cell means) across these conditions. Consistent with prior research, the model provided a reasonable prediction of intentions ($R = .73$, $p < .001$). Support for the normative weight's validity was attained as only the attitudinal component received a significant ($p < .01$) weight while the normative weight was clearly insignificant. It should also be noted that, in this situation, the regression and correlational analyses were consistent as A_B achieved a significant ($p < .01$) correlation ($r = .72$) with intentions while SN did not ($r = .08$).

Study II²

Method

Subjects and Procedures. A total of 193 male and female undergraduate marketing students participated in the experiment. Each subject read one of four different scenarios in which a hypothetical woman was considering the purchase of a dress and that a female neighbor who was accompanying this woman thought she should purchase the dress. The four scenarios represented the product of a 2 X 2 manipulation of the scenario content. The first manipulation, No Manipulative Intent (NMI)--Manipulative Intent (MI), refers to the presence or absence of information that the woman's neighbor was exerting influence for self-serving reasons. The second manipulation, Agree-Disagree, altered the statement describing the woman's attitude toward the dress from positive to negative. Upon completion of the scenario, subjects were asked to play the role of this woman in responding to a questionnaire containing the measures necessary for operationalizing the FBI model. At this point, a third manipulation was introduced as subjects responded to one of three possible questionnaires that differed in the level of specificity at which MC was assessed (i.e., general, moderate, and situation specific). This factor was included since there presently exists some disagreement as to which level of measure specificity is most appropriate (cf. Ahtola 1976; Fishbein 1976; Glassman and Fitzhenry 1976; Miniard and Cohen 1981).

Measures. Subjects first responded to one of three alternative measures of MC via 7-point scales ranging from "I want to do" (+3) to "I want to do the opposite of" (-3). Depending upon whether level of specificity was general, moderate, or situation specific, the scale was prefaced by either "In general", "In the area of clothes shopping behavior", or "In this situation", respectively. Next, NB was assessed on 7-point scales with the endpoints "I should" (+3) and "I should not" (-3). NB and MC were obtained for three referents: the hypothetical woman's neighbor, husband, and parents. Subjects then reported their attitude toward the behavior on four 7-point bipolar evaluative semantic differential scales (good-bad, foolish-wise, rewarding-punishing, harmful-beneficial). Subjects

²This experiment has been previously reported (Miniard and Cohen 1979, 1981), although the data were not discussed in light of the present concerns. The reader is referred to these articles for a more detailed discussion of the experimental procedures.

next responded to the SN measure via a 7-point scale ranging from "I should" (+3) to "I should not" (-3). This was followed by an alternative attitudinal measure (PAB) not employed by Fishbein. This measure ("Forgetting what others think you should do and their reaction, you personally feel that buying the dress is:") was designed to minimize the potential for normative contamination by instructing subjects that the influence of others was not to be included in their responses to the measure. The major difference between PAB and AB was that the latter does not suggest that the influence of others is to be ignored. BI was next measured on three 7-point bipolar semantic scales (likely-unlikely, probable-improbable, possible-impossible).

Validation Condition. In addition to examining the impact of the NMI-MI manipulation on BI for inferring the importance of normative influences, further evidence was gathered in the form of subjects' self-reports. An additional 57 male and female undergraduate marketing students participated in this phase. Each subject read one of the four scenarios, responded to a measure of BI, and was then asked to estimate the impact of the social influences depicted in the scenario upon their intentions to purchase the dress via an 11-point scale with the endpoints "more likely to buy the dress" (11) and "less likely to buy the dress" (1). The scale midpoint of this "directional importance" measure was to be circled if such influences were unimportant. If social influences were an important determinant of intentions, subjects' responses to this measure should then significantly differ from the scale midpoint.

Results

Evidence supporting the importance of normative considerations in determining intentions was attained as the cell means for both the NMI ($\bar{X}=8.31$) and MI ($\bar{X}=4.14$) scenarios significantly ($p < .05$) differed from the scale midpoint (i.e., 6). Further support for the salience of social influences was also attained as the NMI-MI manipulation had a highly significant ($p < .001$) effect upon intentions and explained 16% of the variability. These findings suggest that the normative component should receive a significant regression weight.

^bStandardized partial regression coefficient for normative model component.

^cPooled simple correlation (i.e., multicollinearity) between attitudinal and normative components.

* $p < .05$
** $p < .01$

Given the two alternative attitudinal measures (i.e., AB and PAB) and the four different normative representations (i.e., SN and the three Σ NBjMCj formulations that differ in the level of MC specificity), a total of eight regression models were tested. The results of these pooled regression analyses for the various attitudinal and normative operationalizations are summarized in Table 2. Focusing on those models employing Fishbein's standard AB measure (i.e., models 1-4 in the table), the FBI model fails to correctly identify the importance of normative influences when either SN (model 1) or a general level of MC specificity (model 2) is employed for operationalizing the normative component as an insignificant normative weight was attained for these models. Interestingly, replacement of AB by PAB (which is significantly less correlated with SN) improves the FBI model's diagnostic performance when SN is employed for representing normative influences. While the normative weight was insignificant for the AB + SN model, the weight attained significance for the PAB + SN model. With respect to the correlational results, all of the normative measures except for the Σ NBjMCj formulation where MC was assessed at a general level correlated significantly ($p < .05$) with intentions. Thus, in the one instance where the correlational and regression analyses conflicted (i.e., model 1), the correlational analysis was correct.

Conclusion

The ability of the FBI model to validly represent the importance of normative influences in two distinct situations was examined. Although the model correctly identified the lack of salient normative influences, inadequacies were found for certain normative operationalizations when normative influences were an important determinant of intention. Evidence relevant to the appropriate level of MC specificity was also uncovered as the general level failed to reflect the importance of social influences whereas the moderate and situation specific levels did adequately represent such influences. These results can be attributed to the fact that some of the experimental conditions (i.e., the MI conditions) under which MC was assessed involved situations where a generally positive referent became negative. The general level, which does not ask subjects to report the situational importance of a referent, was apparently unable to reflect these situational variations in the referent's influence potential. Since the normative component received an appropriate weight when either of the two remaining levels of MC specificity were employed, these findings suggest that such levels are perhaps most appropriate for measuring MC.

One interesting question that arises is why the normative component, when represented by SN, performs accurately under conditions lacking social influences but is inaccurate under settings involving salient normative influences. One possible explanation is the multicollinearity between the attitudinal and normative components. In Study I, AB and SN were unrelated ($r = -.90$). In Study II, however, there was a significant correlation between the two measures (as reported in Table 2) thus indicating that the likelihood for diagnostic error increases in situations where the components are not independent.

While the present findings do shed some light on an area that has thus far been ignored, it is clear that further work will be necessary before the FBI model can be confidently used as a diagnostic tool for identifying the importance of attitudinal and normative influences. Possible areas of improvement over the present studies could involve the use of more natural (i.e., non-role playing) settings that allow a test of the weights' ability to represent the absence or presence of salient attitudinal and normative influences within the same experimental framework rather than comparing across data sets. Research that identifies the conditions under which the model will

or will not accurately identify the importance of these influences would seem to hold the greatest promise.

A COMPARISON OF TWO BEHAVIORAL INTENTION MODELS

David Brinberg, University of Maryland

Abstract

The present investigation compared the predictor variables of Fishbein's and Triandis' behavioral intention models. The distinction Triandis makes concerning affect (gut feeling) was supported, that is, affect and attitude were found to measure two dimensions. In addition, the social influence constructs of both models seem to measure two dimensions: (1) what relevant others think and (2) what is appropriate to do.

Introduction

In recent years, there has been increased interest in determining the extent to which verbal reports, survey results, and attitude measures can predict behavior. Numerous models have been developed to predict behavior, and recently, some of these models have been compared (Zuckerman and Reis 1978; Jaccard and Davidson 1975; Brinberg 1979). The primary interest of these researchers comparing models was examining the relationship between the predictor variables and the criterion within each model. In other words, the researchers were interested in comparing the outcome of one model's predictions with the outcome of comparable predictions from the other models. For instance, in the studies cited above, the comparison of the different models involved comparing the multiple correlation (i.e., the percent of variance accounted for in the criterion) or the population estimate of the mean square error.

Often ignored are the relationships among two(or more) sets of predictor variables from the two(or more) models. It is possible that the outcome (e.g., multiple correlation) from a set of models are different(same) even though the predictor variables measure the same (different) underlying dimension(s) (Brewer, Campbell, and Crano 1970; Birnbaum and Mellers 1979). Thus, independent of the models outcomes, substantial similarities (or differences) may be found among the models. Since the dependent variables for these models are the same, differences between these models can exist: (1) among the predictor variables or (2) among the relationships of these predictor variables with the criterion. The major focus of this paper will be on the relationships among the predictor variables. The two models selected for comparison in this study are proposed by Fishbein (Fishbein and Ajzen 1975) and Triandis (1977). These models have been examined in a number of cultures (Davidson, Jaccard, Triandis, Morales, and Diaz-Guerrero 1976; Davidson and Jaccard 1975), with a number of behaviors (Songer-Nocks 1976; Zuckerman and Reis 1978; King 1975; Pomazal 1974) as well as compared using different behaviors (Jaccard and Davidson 1975; Seibold and Roper 1979; Brinberg 1979). However, in none of the studies comparing these two models was an attempt made to determine the interrelationships among the various predictor variables.

Fishbein's Model

Fishbein (Fishbein and Ajzen, 1975) states that a person's intention to perform a behavior is determined by: (1) one's attitude towards the performance of the behavior and (2) one's perception of whether significant others think s/he should or should not perform the behavior.

This model may be expressed by the following algebraic equation

$$\text{Intention} = \text{Attitude}(w_1) + \text{Subjective Norm}(w_2) \quad (1)$$

The attitude is viewed as a function of the beliefs concerning the act multiplied by the evaluative aspect of the beliefs. This may be represented as follows:

$$\text{Attitude} = \sum b_i e_i \quad (2)$$

where b_i = likelihood that performing the behavior will result in some outcome, e_i = evaluation of that outcome. The subjective norm consists of normative beliefs of significant others multiplied by the motivation to comply with these others. This may be represented as follows:

$$\text{Subjective Norm} = \sum N_b M_c \quad (3)$$

where N_b = belief that a particular referent thinks you should or should not perform the behavior, M_c = motivation to comply with that particular referent.

The w_1 and w_2 constructs are theoretical parameters reflecting the importance of the variables in determining intention. They are generally determined through regression techniques.

Triandis' Model

Triandis (1977) states that the determinants of a person's intention may be expressed by the following set of equations.

$$\text{Intention} = A(w_3) + C(w_4) + S(w_5) \quad (4)$$

where A = affect towards the behavior, that is, perceived enjoyment vs. disgust associated with performing the behavior, C = the perceived value of the consequences associated with the behavior, S = social determinants.

As before, w_3 , w_4 , and w_5 are theoretical parameters reflecting the importance of the constructs in determining intention. They, too, are generally determined through regression techniques.

The social determinants component consists of a number of constructs: norms, roles, the actor's self-concept, moral norm, ideals, and contractual agreements. In this study, norms, roles, the self-concept, and the moral norm were used as elements of the social component. The definitions of these constructs will be discussed later.

The second equation of the model specifies the "C" component of the first equation. Following instrumentality theory (Rosenberg 1956), this term is operationalized as follows:

$$\text{Consequences} = \sum p_c v_c \quad (5)$$

where p_c = likelihood that a behavior will result in some outcome, v_c = evaluation of that outcome.

Comparison of Fishbein's and Triandis' Models

One difference between Fishbein's and Triandis' models concerns a distinction between affect and attitude (evaluation). Triandis (1977) defines affect as the "gut

feeling" associated with the behavior and distinguishes this from attitude (evaluation). Evaluation, according to Triandis, is a cognitive judgment based on $\Sigma p_c v_c$. Triandis (1977) justifies this distinction by arguing that for some types of behaviors (e.g., sin and/or duty), both constructs will make separate contributions in predicting intention. Fishbein, on the other hand, has argued that both affect and attitude measure the same underlying evaluative dimension. Therefore, it is not necessary to postulate separate constructs since each is measuring the same underlying dimension. (It is important to note that $\Sigma p_c v_c$ is equivalent to $\Sigma b_i e_i$ and is used interchangeably throughout this paper.) Based on these hypothesized relationships, one aspect of this study will examine whether a single or multiple dimension can be used to describe affect, attitude, and consequences ($\Sigma b_i e_i$).

A second difference between these two models involves the normative component in Fishbein's model and the social determinants in Triandis' model. Fishbein's approach implies that the normative component is an indicant of what relevant others think. According to Fishbein (Fishbein and Ajzen 1975), the subjective norm measures "what most people who are important to me think I should do." This subjective norm is hypothesized to be determined by normative beliefs (what a particular referent thinks I should do) multiplied by the motivation to comply with that referent. Triandis (1977), on the other hand, defines a norm as the appropriateness of performing the behavior. In addition to norms, Triandis includes other constructs in the social determinants: roles, which is the appropriateness of performing the behavior for a person in a particular position in the social system; self-concept, which consists of beliefs the person perceives concerning the appropriateness of the act for himself(herself); and moral norm, which is the perceived moral obligation to perform the behavior.

All the constructs in both the social determinants of Triandis' model and the normative component in Fishbein's model may be seen to measure a social influence dimension. If this is the case, these constructs should measure the same underlying dimension. Another aspect of this study, then, will examine the relationships among the constructs that are proposed to measure social influence.

Numerous behaviors can be used to test these two models. However, when comparing models, it would be useful to select behaviors that have been examined by each model separately. One behavior that meets this criterion is blood donation (Zuckerman and Reis 1978; Pomazal 1974).

Method

Subjects

Subjects were obtained from the participant pool in partial fulfillment of a course requirement. The data were collected at three points in time, during the course of four months, with a total of 96 subjects completing all three phases.

Procedure

In order to obtain the salient beliefs, 100 subjects, who did not participate in the main phase of this study, were asked to indicate the beliefs they associated with donating blood. Twenty-five subjects indicated their beliefs concerning donating blood in each of three contexts (i.e., in the context of the blood bank, the hospital, and the blood mobile) as well as donating blood in general. The use of these different contexts will be made clear shortly. The subjects were asked to indicate the advantages, disadvantages and consequences of

donating blood. The modal set of beliefs were similar across all contexts. Thus, only one set of beliefs was used as the modal salient set.

Measuring Instrument

All the constructs in both models were measured on 7 point scales. The belief statements were measured on a subjective probability scale (e.g., Donating blood at the blood bank this semester would be painful: likely:unlikely). The evaluation of those beliefs were measured on an evaluative scale (e.g., Doing something painful is: good-bad). Motivation to comply with a referent was measured by asking the subject, "Generally speaking, I want to do what (Referent X) thinks I should do: want to do-want not to do." Normative beliefs were measured by asking the subject, "(Referent X)thinks I should donate blood at the blood bank this semester: likely-unlikely." A person's attitude toward the act (e.g., Donating blood at the blood bank this semester is:) was measured on three evaluative scales (i.e., good-bad, nice-awful, favorable-unfavorable). The subjective norm was measured by asking the subject what significant others think s/he should or should not do (e.g., Most people who are important to me think I should donate blood at the blood bank this semester: likely-unlikely). The subject's intention was measured on a subjective probability scale (e.g., I intend to donate blood at the blood bank this semester: likely-unlikely).

The affect construct in Triandis' model was measured using scales intended to measure the person's "gut" feeling (i.e., enjoyable-disgusting; pleasant-unpleasant; exciting-nauseating). Roles, as conceptualized by Triandis measure the appropriateness of the behavior for a person in a particular position in the social system (e.g., It is appropriate for students to donate blood at the blood bank this semester: appropriate-inappropriate). Moral norm was measured by asking the subject, "I have a moral obligation to donate blood at the blood bank this semester: have a moral obligation-have no moral obligation." The attributes used to measure the self-concept were obtained in the aforementioned elicitation phase (e.g., I consider myself the type of person who is concerned: likely-unlikely).

Results

In order to determine the generalizability of these models across situations, blood donation was examined in the context of the blood bank, the hospital, and the blood mobile. The predictive accuracy of both models was assessed and found not to be systematically different (R^2 for both models was approximately 30%). Since the main intent of this paper is the examination of the interrelationships among the different predictor variables of both models, the predictive accuracy of these models will not be discussed. The reader interested in a detailed presentation of the predictive accuracy of these models should see Brinberg (1979).

As mentioned earlier, Triandis draws a distinction between affect and attitude whereas Fishbein sees both constructs as measures of the same underlying evaluative dimension. In order to examine this theoretical distinction, two approaches may be used. The first would be to place the attitude and affect measures in a regression analysis and determine whether both make independent contributions in predicting intention. However, as pointed out by Brewer et al. (1970), Kenny (1976) and Birnbaum and Mellers (1979), interpreting the pattern (significance) of regression weights may lead the researcher to mistakenly interpret that more than one factor underlies a set of constructs. Since the regression technique does not allow for the effects of

measurement error, a researcher may conclude that two (or more) constructs exist, when, in fact, the constructs are imperfect measures of the same underlying dimension.

To circumvent some of the limitations of the regression technique, Brewer et al. (1970) suggest using a factor analytic approach to determine the number of factors underlying a set of constructs. Since a unique algebraic solution is always available for three variables (Brewer et al. 1970), it was decided to factor analyze the scales used to measure affect and attitude as well as $\Sigma b_i e_i$ in order to determine whether a single factor can be used to account for the relationships among these constructs. Table 1 contains a varimax rotation of a principal components analysis of attitude, affect, and consequences.

TABLE 1
VARIMAX ROTATION OF PRINCIPAL COMPONENTS ANALYSIS OF ATTITUDE, AFFECT AND CONSEQUENCES FOR THE INTENTION TO DONATE BLOOD

A maximum likelihood factor analysis (Lawley and Maxwell 1971; Joreskog 1967; Humphreys and Montanelli 1975) was used to determine the number of factors underlying these concepts since it provides a χ^2 goodness of fit test for any K factor model. If the χ^2 value obtained from this analysis is significant for K factors, this indicates that at least K + 1 factors are needed to adequately fit the data, that is, a significant χ^2 indicates that a significant portion of the variance can still be systematically accounted for by extracting another factor. Thus, the number of factors used as an adequate fit of the data occur for the first non-significant χ^2 value.

For the factor analyses reported in Table 1, all yielded a significant χ^2 for the first factor ($p < .01$) and all but one yielded a non significant χ^2 for the second factor. The significant χ^2 for the second factor was in the context of the blood mobile at time 3 ($\chi^2 = 17.63$, $p < .05$). The χ^2 for the third factor was non-significant.

The findings from the maximum likelihood factor analysis indicate that two factors consistently provide a sufficient fit of the data. Based on the pattern of factor loadings found in Table 1, the first factor appears to measure an affect dimension, that is, the bi-polar adjectives specified a priori to measure affect (Triandis 1977), all loaded on the same dimension. The second factor appears to measure an evaluative dimension since the good-bad scale (which Fishbein uses as a measure of attitude) consistently has a high loading.

An alternative explanation to account for the pattern of factor loadings (i.e., the emergence of two factors) is that it is an artifact of the response language used by the subject. In other words, two dimensions may emerge since one set of adjectives (e.g., affect) have a greater subjective range than another set (e.g., attitude). However, the plausibility of this alternative explanation is reduced since an independent assessment of attitude (i.e., $\Sigma b_i e_i$) is consistently loaded with the attitude scales. This provides additional evidence for describing the second factor as evaluative.

Thus, based on the pattern of factor loadings as well as the maximum likelihood factor analysis, Triandis' distinction between affect and attitude is supported since two factors, not one, are needed to adequately describe the data.

The relationships among the constructs in Triandis' social determinants component as well as Fishbein's normative component also need to be examined in order to determine the number of dimensions underlying these concepts. Triandis has postulated that moral norm, roles, norms, and the self-concept can be summed to form an index of social determinants. This implies that these constructs measure the same underlying dimension. In order to determine the relationships among these constructs (along with Fishbein's normative measures) the same factor analytic techniques described earlier were used. Tables 2 contains the varimax rotation of a principal components analysis of the constructs that measure social influence.

A maximum likelihood factor analysis was performed in order to determine the number of factors that would adequately describe the data. In all cases, the χ^2 value for the first factor was highly significant ($p < .01$) and non-significant for the second factor. These patterns of results indicate that a two factor solution can be used to describe the constructs that measure social influence. This is contrary to Triandis' assumption that the moral norm, roles, norms, and the self-concept are measuring a single dimension. Based on the pattern of factor loadings found in Tables 2, the first factor appears to measure a dimension that deals with the appropriateness of the behavior, since norms and roles have a high loading on it. The second factor appears to measure what "relevant others" think since the subjective norm and ENbMc have a high loading on this dimension. Interestingly the moral norm generally has a high loading on this dimension. This suggests that people view a moral obligation as something society thinks they should do, in other words, measuring what relevant others think.

TABLE 2
VARIMAX ROTATION OF PRINCIPAL COMPONENTS ANALYSIS OF
SOCIAL INFLUENCE CONSTRUCTS FOR THE INTENTION TO
DONATE BLOOD

Time 1

scale	Blood Bank		Hospital		Blood Bank	
	F.L. 1	F.L. 2	F.L. 1	F.L. 2	F.L. 1	F.L. 2

Self-Concept	.48	.23	.46	.35	.51	.22

Time 3

Subjective Norm	-.11	.89	.11	.82	.14	.91
ENbMc	.15	.84	.04	.86	.17	.89
Moral Norm	.23	.69	.27	.66	.37	.63
Role Norm	.94	.13	.92	.18	.91	.21
Self-Concept	.32	.50	.23	.47	.42	.39

In summary, a single factor solution was not adequate to describe the relationships among the social influence constructs. Based on the maximum likelihood factor analysis, two factors were adequate to describe the data. These factors appear to measure: (1) what relevant others think and (2) what is appropriate to do.

Discussion

Based on the factor analyses of attitude, affect, and consequences two dimensions, not one, appear to be sufficient in describing the relationships among these constructs. This result is contrary to Fishbein's assumption that all three are measuring the same underlying dimension and supportive of Triandis' assumption that these constructs may be separated into two dimensions; affect and attitude.

A similar analysis of the social determinants in Triandis model and the normative components in Fishbein's model shows that two dimensions, not one, are needed to account for the relationships among these constructs. This is inconsistent with Triandis' assumption that the constructs of the social determinants component measure a single underlying dimension. The two dimensions appear to measure: (1) what relevant others think and (2) what is appropriate to do.

An implication of these findings is that neither model, alone, can account for the relationships among these constructs. This suggests that a composite model, incorporating features of both models may be used to predict intention. This composite model would contain: (1) an affect construct, (2) an attitude construct, (3) a "relevant others" construct, and (4) an "appropriateness"

construct. A preliminary analysis of this composite model indicated that it was an accurate predictor of intention and consistently was more effective in predicting intention than either Fishbein's or Triandis' model. However, the magnitude of this difference was small and it is possible that this composite model was "better" since it was tested in the same sample in which it was developed. Future research is necessary comparing this composite model with Fishbein's and Triandis' model in order to determine whether it is useful to integrate these two approaches in predicting intention.

Finally, past research (e.g., Jaccard and Davidson 1975, Seibold and Roper 1979) has focused on the comparison of the predictive accuracy of these two behavioral intention models and has found both models to be superior to the other in predicting intention. What the present study suggests is that substantial similarities and differences may be found among these models by examining the relationships among the predictor variables. Therefore, it is strongly recommended that researchers interested in comparing different models (which have the same criterion), examine the relationships among the independent variables in addition to examining the relative predictive efficiency of these models.

A DISCUSSION OF ATTITUDE RESEARCH AND
BEHAVIORAL INTENTIONS

Paul R. Warshaw, McGill University

Abstract

Each of the three papers in this session focus upon issues related to the determinants of behavioral intentions. Holbrook et.al. focus upon attitude formation. Specifically, the role of attribute importance in attitude structure is addressed. Brinberg looks more at the dimensionality of attitudes and norms. Employing Fishbein's and Triandis' models he shows both attitude and normative constructs may be bi-dimensional. Miniard, on the other hand, questions whether measured attitudes and norms are really independent factors of intent.

Attitude Structure and Search:
An Integrative Model of Importance-Directed
Information Processing

The Holbrook, Velez and Tabouret paper examines how attribute importance is related to attitude structure. While the study essentially replicates (with some methodological improvements) an earlier piece by Holbrook and Maier (1978), the findings are quite interesting and highlight some theoretical and methodological issues that consumer researchers should attend closely. The primary thesis of Holbrook et.al. is that product attributes vary in their importance to consumers. That is, some attributes are perceptually more important than others in determining product-related attitudes. The principal is certainly not novel, since attitude researchers have long acknowledged this fact. The concept is an outgrowth of Fishbein's proposition that attitudes are formulated from a small set of salient beliefs. However, the Fishbein approach assumes that once an attribute is incorporated within the salient set, its only contribution to attitude comes from the subjective probability of it being associated with the target object or action and its goodness or badness. Other researchers, quite naturally, became intrigued with the notion that there must be some hierarchical importance structure among those attributes in the evoked set. After all, since the evoked set contains approximately 5-9 attributes, the remaining attributes are tautologically non-important. If so, doesn't it logically follow that the salient attributes are similarly disectable into most important and least important classes? In concert with this line of reasoning, attempts have been made to secure attribute importance ratings from subjects and to use these ratings as weights in expectancy value or other type attitude models. The problem is that importance weight inclusion does not seem to enhance predictions of affect. The Holbrook et.al. paper proposes and tests a conceptual framework for resolving this seemingly perplexing issue. They claim that attribute importance has a major impact, but not within the model structure per se. Rather, importance relates more directly to information search processes. That is, the more important an attribute, the more information is gathered about it, with attitudes formed thereafter on the basis of cues acquired about these important attributes. The study was fairly well done and seemingly verifies the authors' model. More significant, it implies an issue that consumer researchers have too often ignored. A common practice in marketing and related disciplines is for researchers to haphazardly decide that some variable (e.g., a personality trait like self-confidence) is related to some aspect of consumer behavior (e.g., purchase of name-brand goods). Typically, there is no systematic, careful development of theoretical

linkages between the variables studied (cf. Kassarian 1971). Rather, in knee jerk fashion, the variable is tossed into some equation model in an additive or multiplicative fashion (without theoretical rationale) and run through a regression to see if significant betas pop out. Alternatively, some type of discriminant, factor or canonical analysis is conducted to delineate 'underlying factors or relationships'. The results are typically meaningless and not at all generalizable. This scenario is typical of marketing studies pertaining to attitude theory issues. The so-called importance weight debate is no exception. Hence, in my opinion, the greatest contribution of the Holbrook et.al. manuscript is its orientation toward building theoretical linkages in systematic, logical fashion. This tight approach is certainly more difficult and time consuming, and requires broader literature reviews than the alternative approach which is based mainly on personal opinion, scant surveys of existent research and frantic applications of the 'latest', 'hottest' data analysis techniques.

The paper has some other features I'd also like to highlight:

1. An interesting methodological technique is presented that might usefully be employed by other researchers. Namely, use of a sticker-pulling procedure in a mail-survey questionnaire was attempted (apparently quite successfully). This raises the possibility of conducting studies by mail that heretofore required laboratory settings. A major feature of social science research is that most studies employ relatively small, student samples. This creates many problems (e.g., nongeneralizable results, sensitized subjects, lack of statistical validity, etc.). Everyone would like to use large, representative samples but the dollar costs are typically prohibitive (especially where laboratory type formats seem warranted). Experimentation by mail certainly allows for better and larger sampling. The current sticker-pulling technique and further developments along these lines could help bring the laboratory to the people in an inexpensive, simple manner.
2. Part strength and part weakness of Holbrook et.al. was that the authors were stately aware of certain key assumptions inherent in their methodology. For example, "it is assumed that the respondent believes the information he has received to be true...". It would have been better methodology to verify this assumption during debriefing. Many consumer researchers are unaware that this and other key assumptions are integral components of their research design. This is particularly true when treatment manipulations entail differential communications across subject groups. Without appropriate manipulation check analysis (which includes believability questions), one may not justifiably conclude that the findings resulted from the stated treatments. Rather, all sorts of demand characteristic and other explanations are equally possible, thereby threatening the experiment's internal validity. While Holbrook et.al. recognized the problem, they did not attempt to ameliorate it. Similarly, the authors correctly acknowledge that they are assuming subjects assigned a subjective probability of 1.0 to each cue, and that inferential beliefs may have been generated but were unassessed

by the research instrument. It is meritorious that Holbrook et.al. were aware of these assumptions, but it would have been much better to have dealt directly with these issues or, at the least, to explore them via manipulation checks.

A Comparison of Two Behavioral Intention Models

Brinberg's paper compares the Fishbein and Triandis intention models. Results purportedly support Triandis' notion that affective and evaluative components of attitude should be measured separately. Further, contradicting both models, Brinberg finds two dimensions of social influence (whereas both Fishbein and Triandis postulate alternate unidimensional constructs). However, when Brinberg attempts to predict intent from the revealed attitudinal (two) and social influence (two) dimensions, only small predictive improvements are realized.

This is certainly an interesting paper for consumer researchers, but not because the study itself evidences exceptional methodology or creative insight. Rather, its greatest contribution stems from the fact that it brings the Triandis model to the attention of the ACR audience. One major blind spot among marketing researchers concerns their acknowledgement and study of existing non-Fishbeinian type intention models. Unfortunately, most attitude researchers in management departments are totally unaware of the existence of these competing paradigms. Typically at best, only the Fishbein model is cited, and then frequently in erroneous fashion. Hence, Brinberg's conference paper performs the valuable function of publicizing one of the important alternate conceptualizations of intent. Let me take this opportunity to point out other models that consumer researchers should attend: Wickers paradigm incorporating judged influence of extraneous events (e.g., Wicker 1971); Schwartz's model, which discusses moral norms and ascription of responsibility, and Snyder's use of self-monitoring as a moderater variable (cf. Zuckerman and Reis 1978); Sheth's model (Raju, Bhagat and Sheth 1975); and Warshaw's behavioral intention paradigm (1980). While some of these approaches are on stronger conceptual footing than are others, each adds something to our understanding of attitudes and intentions. Hence, consumer research in this area would be enriched considerably by conscientious attention to all competing theoretical tracks.

Concerning Brinberg's research per se, a few limitations seem evident:

1. Disecting and separately measuring both affective and evaluative dimensions of attitude may be necessary only for a restricted class of behaviors. As defined by Triandis and herein applied, affect concerns strong emotional states associated with some criterion act (e.g., disgust, nausea). While these feelings may be germane and present within certain behavioral contexts (e.g., blood donation, hospital volunteer work, purchase of pornographic material), such strong affective responses are unlikely to be associated with most product-related settings. Hence, the author's findings may have limited applicability for the bulk of consumer research. Nevertheless, this is primarily an intuitive hypothesis on my part and is not intended to deprecate Brinberg's results. Certainly, further work is merited on the affect versus evaluation issue.
2. I have strong reservations concerning some of Brinberg's questionnaire items. For example, Fishbein's Aact was measured by the following item: "Donating blood at the blood bank this semester is good-bad, etc.". However, the criterion act concerns subjects' own intentions to donate blood. Clearly, a person might claim that 'donating blood' is good but ascribe non-intent to personally donate blood. The problem

here is that the target of Aact and BI differ. While Aact concerns the general concept of blood donation, BI focuses upon the target person per se. Ajzen and Fishbein (1977) clearly point out the necessity of employing the same target, object, time and context for both Aact and BI.

Similarly, Brinberg employs an imprecise intent measure. That is, he assesses intent by the following item: "I intend to donate blood at the blood bank this semester: likely-unlikely". This measures the likelihood that the subject will intend to donate blood, not the likelihood that he/she will donate blood. Clearly, these are not equivalent, and accurately measuring subjective probability of behavior requires the latter 'will donate' format. To clarify the distinction, think of a person who is self-professedly likely to intend to stop smoking, but admits that the probability of his stopping smoking is meager. Part of the problem here is that Triandis' definition of intent is not directly comparable to Fishbein's parallel measure. Brinberg uses the Triandis measure but then relates both Triandis' and Fishbein's independent variables to this singular construct. Fishbein's subjective probability of behavioral performance is more akin to the objective, derived probability of behavior (Pa) variable in Triandis model (where Pa equals the sum of habits (i.e., the number of times the behavior has been performed in the past) and intent multiplied by a facilitating conditions measure). Hence, to be fair, Brinberg should have employed two alternate items to assess 'intent'.

Finally, I am unconvinced that appropriate scales were used to measure affect (gut feeling). The adjective sets 'enjoyable-disgusting' and 'exciting-nauseating' do not constitute bipolar adjective pairs. 'Disgusting' is not the opposite of 'enjoyable' (in fact, some acts may be enjoyable because they are disgusting). Similarly, exciting and nauseating may be quite unrelated. A better pair, for example, would be exciting-dull. Hence, interpretation of revealed factors is subject to debate.

Hence, the present study has sufficient instrumentation problems to render suspect the thrust of its conclusions. Nevertheless, the issues raised are important and justify additional research employing multiple types of behavior.

Examining the Diagnostic Utility of the Fishbein Behavioral Intention Model

Miniard's piece contains a rather lengthy review of evidence concerning the validity of Fishbein's behavioral intention model. While far from exhaustive, this literature review is certainly the strongest aspect of the paper. Miniard's experiments, on the other hand, are very troublesome. Their stated purpose is to ascertain whether the social norm (SN) measure receives a significant regression weight when social influences 'do affect' intentions but is nonsignificant when social influences don't impact upon intent. However, methodological deficiencies, questionable logic and inattention to recent published research negate the usefulness of these studies.

Regarding Study I, the following problems seem evident:

1. In the 'others expectations unknown' treatment, Miniard claims the situation is devoid of information concerning the social environment. Without sufficient manipulation checks (which apparently weren't done), this is an unwarranted claim. The role playing scenario format makes this a projective technique. As in all such artificial, 'pretend' tasks, a wide range of inferences, projections from past experiences and other situation-structuring cognitions are triggered. Hence, it is unreasonable to assume that subjects perceived a blank, featureless social

environmental context. If one wants to make this rather counterintuitive claim, manipulation check verification is imperative.

2. Similarly, there were no manipulation checks for the "others expectations 'positive' and 'negative'" treatments. Given the nature of the research hypotheses, it is necessary to verify whether subjects believed and accepted these statements as factual truths. If subjects did, in fact, believe these statements, then the subsequent disclaimer, "of course, what others feel you personally should do here is of no concern to you" is highly unlikely to negate fully the normative manipulation. If so, this is not a 'no normative influence' experiment (as Miniard claims) and SN should relate to BI. Since this did not occur, I suspect that subjects were not properly manipulated into perceiving differential 'others expectations'. If so, the treatments are invalid. Nevertheless, this still may serve as a no-influence experiment. Lack of a significant beta weight on SN and n.s. cor (SN, BI) reinforce this conclusion. However, the logic behind the experimental format seems highly questionable. Why bother to manipulate normative influences here? If the sole purpose was to demonstrate that SN is nonsignificant in contexts devoid of social influence, a simple, more tightly controlled design would surely have sufficed.

Essentially, my primary criticism here is that the author makes a lot of claims about what people were thinking and how they approached the task without any sort of verification via debriefing procedures. Without this structure, numerous explanations for the findings are possible.

Study II constitutes a reanalysis of previously published data. Miniard claims that the experimental format implies the existence of social influence. Hence, SN should correlate with BI and carry a significant regression weight. Once again, there are methodological problems and strained logic:

1. Since the role-playing scenarios depicted some hypothetical female buying a dress, why were both male and female subjects employed? This task is so external to the experience of most males that their responses would clearly represent projections of stereotypic 'female' behavior rather than their personal cognitive processes. Females, on the other hand, are likely quite familiar and experienced with the scenario settings. This familiarity probably generated projections from similar experiences in memory. Hence, their responses might be based on factors external to the treatment manipulations. Given that the task was so different for males than females, either only female subjects should have been used (with extensive manipulation checks), or else data should be analyzed separately for males and females.
2. Miniard only manipulated situation-specific information concerning the neighbor. However, NE and MC were additionally measured for the hypothetical woman's husband and parents. This creates several problems. First, SN is supposed to concern subject's perceptions of his/her 'most important others'. Miniard is assuming that neighbor, husband and parents are the 'important set' for each subject. This claim is only justified if verified by manipulation checks, since there is good cause to believe that some or all of these 'referents' may be irrelevant for dress buying. Further, what about the woman's 'best friends'? They might be expected to be highly important others.

Further, Miniard had 57 additional subjects read the scenarios and estimate the impact of the social influences in the scenario on their BIs. Finding differences between NMI and MI, Miniard claims social influence was important in the scenario settings. However, social influence in the treatment paragraphs involved only the neighbor, while the measuring instrument assessed attributions concerning husband, parents and most important others as well as the neighbor. To say the neighbor exerted social influence is not equivalent to saying that a measure which incorporates the neighbor and several other referents is related significantly to BI. Hence, there is no compelling justification for Miniard's hypothesis that SN should receive a significant beta weight. If SN only concerned the neighbor, then this postulate might be warranted. But, SN includes attributions to many others besides the neighbor, and in a projection task, these other attributions are unlikely to remain constant across treatments. Miniard, unjustifiably, implicitly assumes this constancy condition.

Hence, Miniard's claim that versions 1 and 2 of the FBI model fail to correctly identify the importance of normative influences is highly suspect. Since SN includes important others, the neighbor may or may not be included in this set. Further, since no information concerning husband, parents and other friends was given, SN is probably largely a projection of one's own A_B , which would imply high $cor(A_B, SN)$, where A_B dominates and thus receives the significant beta weight. The nonsignificance of model 2 simply shows that general MC is unrelated to influence in this particular situation (which is not surprising given lack of general information about any member of the offered referent set). The significant results in models 3 and 4 support this analysis (in each case there was significant $cor(SN, BI)$ and SN had a significant beta). That is, treatment information was situation-specific, and when MC was similarly specific, having only data on the neighbor gave this referent a dominant influence on SN, which then behaved in line with expectations. The 57 subject influence check implied that this would occur, but did not imply that when general SN or MC were employed, significance would result. Only when measures were specific enough to capture the neighbor's stated influence in these specific treatment situations was SN likely to be significant - and it was.

The only point Miniard really makes is that SN and A_B are typically correlated, which questions the assumption that A_B and SN are independent components of intent. However, this issue has been covered extensively in Warshaw (1980) and elsewhere. The real issues, such as separating out identification, internalization and compliance aspects of normative influence were not even touched upon by Miniard.

ATTITUDE RESEARCH AND BEHAVIORAL INTENTIONS:
A CRITICAL REVIEW

Jeffrey E. Danes, Virginia Polytechnic Institute and State University

Abstract

This paper reviews the work by Holbrook, Velez, and Tabouret, "Attitude Structure and Search: An Integrative Model of Importance-Directed Information Processing," Brinberg, "A Comparison of Two Behavioral Intention Models," and Minard, "Examining the Diagnostic Utility of the Fishbein Behavioral Intentions Model."

Attitude Structure and Search

Holbrook, Velez, and Tabouret begin their paper with the following statement, "In spite of extensive research on multiattribute attitude models and information-acquisition paradigms, the linkage between these two important facets of buyer behavior is not well understood." Later on they assert, "...Multiattribute Attitude Research has tended to focus primarily on the static structure of attitude while neglecting the process by which new information inputs are incorporated into the determination of affect" (emphasis added).

At the conceptual level, Holbrook, et al move away from a static description and provide a process, dynamic view of the linkages between information and attitude. One would expect, therefore, that dynamic information-attitude models would be presented to compliment their conceptual work. Unfortunately, this was not the case. The four algebraic multiattribute attitude models appear as static representations of attitude. The modeling work provided by Holbrook, et al could be improved if dynamics were explicitly incorporated into their four models. We now address this issue.

A Dynamic Representation

Holbrook, et al presented four multiattribute models to predict attitude after individuals have acquired information (messages) about a product: a full and partial additive model and a full and partial averaging model. What is the attitude value before information (messages) is received? Holbrook, et al do not address this issue, and neither do they identify or develop multiattribute models that gives us the pre-information search (pre-message) attitude. It is argued below, however, that they implicitly assume that pre-message attitude is given by Fishbein's model (or an "averaging" variant of his model). Without loss of generality, let us restrict our discussion to Holbrook's, et al partial additive model.

After individuals acquire information (receive messages) about the object; Holbrook, et al, assumed that if the message, m , associates an attribute with an object, the new belief value equals 1. Or, if the message disassociates an attribute with an object, the new belief value equals -1. Evaluation, e , is not affected by the messages. The post-message attitude as given by Holbrook's, et al, partial additive model may be expressed as:

$$\text{Post message } a = \sum_k \text{ post-message } b_k e_k \text{ acq}_k, \quad (1)$$

where, a is the attitude toward the object, b is belief, e is evaluation, and acq is the information (message) variable which is coded 1 or 0 depending upon whether the message was received.

$$\text{acq} = \begin{cases} 1, & \text{if information was acquired} \\ 0, & \text{if otherwise} \end{cases} \quad (2)$$

As stated above the attitude, a , reported in Equation 1 is a post-message or "new" attitude. Also, the belief values are post-message or "new" beliefs. With new notation, let us rewrite Equation 1:

$$\text{New } a = \sum_k \text{ new } b_k e_k m_k, \quad (3)$$

where the message, m , is used denote acquired information, acq . Both new a and new b may be expressed as their pre-message values plus the change, i.e.,

$$\text{new } a = a + \Delta a \quad (4)$$

$$\text{new } b = b + \Delta b \quad (5)$$

where a and b is the pre-message attitude and belief, and Δa and Δb is the change in attitude and belief. If we make the appropriate substitutions, Equation 3 may be expressed as:

$$a + \Delta a = \sum_k (b_k + \Delta b_k) e_k m_k \quad (6)$$

or

$$a + \Delta a = \sum_k b_k e_k m_k + \sum_k \Delta b_k e_k m_k \quad (7)$$

One perplexing problem with the Holbrook et al model is that the message, m , is entered twice in Equation 7. Note here that the pre-message attitude,

$$a = \sum_k b_k e_k m_k, \quad (8)$$

includes the message which the individual has not yet received! It makes more sense to define the pre-message attitude as:

$$a = \sum_k b_k e_k. \quad (9)$$

As implied by Holbrook, et al by Equation 7, change in attitude may be expressed as:

$$\Delta a = \sum_k \Delta b_k e_k m_k, \quad (10)$$

where, Δb stands for change in belief.

How Do Beliefs Change?

Holbrook, et al, explicitly assume that a message changes belief in the direction of the object-attribute association made in the message. They also assume maximum change; hence, the post-message belief is equal to the belief-value communicated in the message. Thus, Holbrook, et al, have simply re-stated Anderson and Hovland's (1957) "Distance-Proportional" Model:

$$\text{New } b = b + \alpha(m - b), \quad (11)$$

or

$$b + \Delta b = b + \alpha(m - b), \quad (12)$$

or

$$\Delta b = \alpha(m - b). \quad (13)$$

Additionally, since the authors assume maximum change, the proportionally constant, α , must equal 1.

$$\Delta b = m - b \quad (14)$$

Replacing $(m - b)$ for Δb in Equation 10 gives:

$$\Delta a = \sum_k (m_k - b_k) e_k m_k, \quad (15)$$

Once again there are two message terms. The first message term was derived directly from Holbrook et al.'s assumptions; the last message term appears to be unnecessary and may be deleted:

$$\Delta a = \sum_k m_k e_k - \sum_k b_k e_k. \quad (16)$$

The model presented in Equation 16 is more consistent, than is Equation 15, with Holbrook's et al. logic and assumptions. More importantly, if we began with Equation 9 and worked to build a dynamic model of the information-attitude process, we would arrive directly at Equation 16--given the belief change assumptions made by Holbrook, et al.

Holbrook, et al. was interested in attitude after messages were received. The "new" or post-message attitude may be obtained by adding Equations 9 and 16; this gives:

$$\text{new } a = \sum_k m_k e_k, \quad (17)$$

where, $m_k = \begin{cases} 1 & \text{if message associates object with attribute,} \\ -1 & \text{if message disassociates object with attribute.} \end{cases}$

Equation 17 produces a numerical result identical to Holbrook's et al. partial additive model. However, the dynamic assumptions made by Holbrook, et al. are explicitly stated in the new model.

Summary

Holbrook, et al. presented a promising conceptualization of the dynamic relation between information acquisition (or message reception) and attribute formation/change. The four algebraic models presented, however, failed to capture the dynamic assumptions asserted in their conceptual work. Our discussion centered upon translating Holbrook's et al. assumptions about the dynamics of the information (message) - attitude process into change equations isomorphic with their assumptions.

Two Behavioral Intention Models

Bringberg's paper compares two models for the prediction of behavioral intentions: the extended Fishbein model and Triandis' model. The major differences between the two models are (1) Fishbein assumes "affect" and "evaluation" are indicators of different constructs; (2) Fishbein asserts "subjective norms" influence behavioral intentions and Triandis argues for "social determinants."

To compare the two models, Brinberg compares the factor structure of the predictor variables. He argues against a standard multiple regression analysis "...since the regression technique does not allow for the effects of measurement error, a researcher may conclude that two (or more) constructs exist, when, in fact the constructs are imperfect measures of the same underlying dimension." This, indeed, is an interesting criticism, for Bringberg puts the blame on regression when the blame ought to be placed elsewhere--on measurement. If Brinberg had obtained reliability coefficients for his scales, he could have used the corrected correlations and standard deviations in his regression analyses. Correlations and standard deviations that are corrected for attenuation (unreliability) are "free" of measurement error. If only standardized regression coefficients are of interest, only the correlation matrix need be corrected for attenuation. The more obvious problems associated with multicollinearity were not addressed.

"To circumvent some of the limitations of the regression technique ..." Brinberg relies on a principle components orthogonal factor analysis (with varimax rotation) of the predictor variables. Two factor analyses were performed, one for evaluation, affect, and consequences. And, one for Triandis' social components and Fishbein's normative components. In each case, two factors were obtained. The first two-factor solution was interpreted as support for Triandis' Hypothesis that the affective and evaluative components are not the same. The second two-factor solution was interpreted as "what relevant others think" and as "what is appropriate to do." Hence, Brinberg argues that both Fishbein and Triandis have misspecified the "social influence" component of behavioral intentions. Warshaw (1981) has criticized the scales used for the measurement of "affect" and "evaluation;" the same criticism may be made for the "social influence" constructs. Brinberg does not cite any evidence for the validity of his measures.

At this point a few questions become apparent:

- (1) Why was a Principal Components Factor analysis used?
- (2) Why was the Factor Analysis constrained to be orthogonal?
- (3) Would an oblique solution yield highly correlated factors?
- (4) What are the relationships between "affect," "evaluation," "social determinants," "subjective norm," and behavioral intentions?

As to the first question ("Why was a principal components factor analysis used") a principal components analysis makes assumptions about the data which may not be true--it assumes perfect measurement. The principal components analysis operates on a correlation matrix with ones in the diagonal; i.e., it assumes the variables are measured without error. Other factor techniques do not make this assumption; perhaps, they should have been explored.

For the second and third questions ("Why was the Factor Analysis constrained to be orthogonal," and "Would an oblique solution produce highly correlated factors") there appears to be no justification for constraining the factors to be uncorrelated. We suspect that "affect" and "evaluation" are highly correlated; likewise that "social determinants" and "subjective norms" are also highly correlated. Brinberg could have performed an Oblique Multiple Groups Factor Analysis (Harmon 1967) and the "natural" factor correlations could have been found. Assuming uncorrelated factors is arbitrary and unjustified.

The last question ("What are the relationships between 'affect,' 'evaluation,' 'social determinants,' 'subjective

norms,' and 'behavioral intentions') could be found using a variety of highly related methodologies: (1) an oblique multiple groups factor analysis followed by a path analysis performed upon the factor correlation matrix of the five constructs, or (2) a multiple indicator path analysis, or to use the newer terminology, a structural equation (causal model) analysis with latent variables.

In summary Brinberg attempted to compare two models for the prediction of behavioral intentions: the extended Fishbein model and Triandis' model. For the comparison of the two models, Brinberg used an orthogonal principle components factor analysis on the predictor variables. Their results were interpreted as support for Triandis' notion that "affect" and "evaluation" are separate constructs; that the "social influence" construct consists of two dimensions: "what relevant others think," and "what is appropriate to do."

Several methodological problems were discussed, including:

- (1) Reliability and validity of measurement;
- (2) Choice of factor analysis technique;
- (3) Use of orthogonal solution;
- (4) Structural equations analysis as an alternate analytic tool.

The Diagnostic Utility Of The Fishbein Model

The purpose of Minard's paper is to assess whether the subjective norm component is detectable when it "is present" and when "it is not present." Minard reports two studies. The first experiment was designed to be void of normative influences; the primary task of this experiment was to assess whether normative influences could be detected. The results of his experiment supported the extended Fishbein model. There are, however, several methodological problems associated with the first study:

- (1) No manipulation checks on the experimental treatments were made; hence, we have no guarantee that normative influences were actually absent;
- (2) The reliability of measurement (apparently) was not assessed. Unreliability may have distorted the obtained omega squared's. (Below we demonstrate such distortion using regression.)

Minard's second study reports a reanalysis of his previous published work. In this study, he asserts that normative influences were present. Two out of four regression analyses, however, failed to detect them. There are three apparent problems with the second study:

- (1) The manipulation may not have been relevant to males.
- (2) The neighbor, husband, and parent significant others were arbitrarily selected. No evidence is given justifying this choice.
- (3) Reliability of measurement is not assessed; the regression analyses were not corrected for unreliability.

The last criticism appears to be widespread in consumer research; thus, let us focus our attention on the impact measurement error may have upon multiple regression. As stated above, two of four regression models failed to detect the expected subjective norm influence. The four models differed in their operationalization of subjective norm. One model contained a direct measure of subjective norm, SN; the others varied in terms of specificity: general, moderate, and situation specific. The direct and general

models failed to receive support. For the direct measure of subjective norm, SN, the β coefficient equaled .08; and the f^2 coefficient for attitude toward behavior, A_b , equaled .55. Unfortunately, Minard does not provide us with his correlation matrix; however, the matrix supplied in Table 1 will be used for discussion.

TABLE 1

Example correlation matrix for behavioral intention, attitude toward behavior, and subjective norm

	BI	A_b	SN
BI	1.00	.612	.463
A_b	.612	1.00	.683
SN	.463	.683	1.00

From Table 1, the following regression weights may be derived: $\beta_{A_b} = .555$ and $\beta_{SN} = .084$. It is assumed, however, that all three measures are perfectly reliable. Could measurement unreliability account for the nonsignificant weight for subjective norm? Indeed it could, and we show such an example below. Minard did not provide reliability estimates for his measures; so let us, for discussion purposes, assume that the reliabilities are: .64, .98, and .68 for behavioral intentions, BI, attitude toward behavior, A_b , and subjective norm, SN. If we replace the diagonal of ones with the reliability coefficients and correct (for attenuation) the off-diagonal correlations, we arrive at the corrected correlation matrix reported in Table 2.

TABLE 2

Corrected correlation matrix for behavioral intention, attitude toward behavior, and subjective norm. Reliabilities are in parentheses.

	BI	A_b	SN
BI	(.640)	.773	.702
A_b	.773	(.980)	.834
SN	.702	.834	(.680)

Does unreliability influence the regression weights? It certainly does! The corrected β coefficient for subjective norm now equals .19 and the corrected β coefficient for attitude toward behavior now equals .62; both coefficients may be significant using Minard's degrees of freedom. Since Minard did not estimate the reliability of measurement or correct his analyses for unreliability, we are unable to assess how much his regression weights were distorted.

In summary, Minard proposed an interesting test of the extended Fishbein model. He presented two studies. The first study was designed to be void of subjective norm information. In this experiment, the extended Fishbein model accurately detected the lack of a normative influence. The second study was designed to produce normative influences; and only two of four tests were able to detect the expected influence. Our discussion centered upon several methodological problems:

- (1) Failure to use manipulation checks or possible irrelevant manipulations;
- (2) Failure to assess reliability of measurement and correct analyses for unreliability.

AN EXPLORATION INTO THE SCALING OF CONSUMERS' INVOLVEMENT WITH A PRODUCT CLASS¹

Peter H. Bloch, Portland State University

Abstract

Product involvement as an explanatory or moderating variable with respect to consumer behavior has recently become a topic of significant interest to marketers. However, the usefulness of the construct in consumer research is yet to be fully realized due to a lack of agreement and rigor in operationalizing product involvement. This paper addresses the need for valid measures of individual differences in involvement for particular product classes and reports on the psychometric development of a prototype scale to assess involvement with automobiles. Findings provide preliminary support as to the scale's reliability and validity.

Introduction

The ways in which consumers are involved with the products they purchase and use has, in recent years, become a subject of increasing interest to consumer researchers. This interest is evidenced by the special sessions on the topic of involvement at the American Marketing Association's 1977 Attitude Research Conference and at the 1978 Conference of the Association for Consumer Research. In addition, journal articles dealing with some aspect of involvement have become increasingly common (e.g., Rothschild 1979b, Tyebjee 1979b, Webb 1979). While in these and other studies, product involvement has been defined in various ways, the definition proposed by Day (1970) is characteristic of several in the consumer literature. Day defined involvement as "the general level of interest in the object or the centrality of the object to the person's ego-structure" (p. 45). Several writers (Bogart 1967, Mitchell 1979) have agreed that involvement reflects the amount of interest evoked by the product while, Day's centrality notion has found support from Tyebjee (1979a) and others (DeBruicker 1979, Houston and Rothschild 1978, Lastovicka and Gardner 1979) who suggested that involvement occurs when a product is related to important values, needs or the self-concept.

To date, involvement researchers generally agree that for consumers as a group, products differ in their tendency to arouse involvement. For example, Robertson (1976) has emphasized the low level of involvement generated by many consumer products. In addition to differences across products, several writers (Houston and Rothschild 1978, Lastovicka and Gardner 1979, Tyebjee 1979a) have suggested that for any particular product class, levels of involvement will differ across consumers. The focus of this research is on this between-individuals perspective.

Reviewing the research on individual differences leads to the conclusion that highly involved individuals engage in more complex purchase decision making (Houston and Rothschild 1978), are more brand loyal (Jacoby 1971), are more likely to be opinion leaders (Corey 1971) and are more likely to generate negative cognitive responses to product-related messages (Houston and Rothschild 1978, Wright 1973) than do persons with low involvement. Given this research stream, product involvement appears to be not only a potentially useful moderating or explanatory variable with respect to consumer behavior, but also a possible basis for segmenting markets.

Despite the promising nature of involvement in consumer research, several authors have noted that its explanatory

¹The author thanks Marsha L. Richins and Robert A. Peterson for their comments and contributions to this work.

potential is, as yet, unrealized due to a lack of consensus and rigor in operationalizing the construct (Mitchell 1979, Ray 1979, Tyebjee 1979b). Although many measures of individual differences in involvement have been proposed since the concept's introduction to the marketing literature, few have been subjected to standard reliability and validity testing and at the present time there is no single, well-accepted involvement measure.²

In light of the prominent measurement difficulties relating to product involvement research, Mitchell (1979) has argued that the "first priority" in future field research in involvement is the development of a scale to measure consumers' involvement with a particular product class or brand (p. 194). He went on to say that only when such a scale is developed and subjected to traditional psychometric testing can product involvement be fruitfully related to other aspects of consumer behavior.

Given this call for action, the purpose of this paper is to report on an attempt to scale consumers' involvement with a particular product class and to provide a prototype involvement scale as one step in the further refinement of the involvement construct. This paper next reports on the development of a scale to measure consumer involvement with automobiles.

Choice of Product to be Studied

In developing an involvement scale, the first critical decision that a researcher faces is whether the measure should be applicable to several products or to a single product. As part of their work on the dimensionality of a product involvement, Lastovicka and Gardner (1979) devised a scale able to tap individual differences in involvement for any product class. The benefits of their measure's generalizability appear to be balanced, however, by the imprecise character of its constituent items. Many of the Lastovicka and Gardner scale items appear ambiguous and may not capture how a consumer really feels about any one product. Examples include: "I can make many connections or associations between experiences in my life and this product" and "use of this product helps me behave in the manner that I would like to behave" (p. 63). When scale items are specific to a single product class, they would appear to be more relevant and meaningful.

In a critique of involvement measures, Ray (1979) posited that such measures should be developed "in individual consumer research application situations" (p. 198). He cited the involvement measure developed by Rothschild (1974) in a study of political races and that used by Webb (1979) in research on a television clutter as particularly effective in that they were tailored to specific research situations. In a similar vein, Mitchell (1979) suggested that future involvement research might be based on the use of a scale(s) measuring the degree of interest or arousal evoked by a particular product class or brand.

A further argument for building a product-specific measure rests on the state of current understanding of the construct of product involvement. As noted by several authors (Lastovicka and Gardner 1979, Houston and Rothschild 1978, Mitchell 1979, Tyebjee 1979b), the literature on involvement

²For a fuller treatment of issues and problems relating to the measurement of involvement, see Mitchell 1979, Houston and Rothschild 1978, and Ray 1979.

is fragmented and for the most part based on measures of dubious quality. Therefore, because involvement theory remains in a developing state, the search for relationships between involvement and other aspects of consumer behavior appears to be worthwhile even if in a product-specific context.

Once the product-specific focus was chosen, the next decision concerned the choice of the product to be studied. After reviewing several possible options, automobiles were selected as the product class of interest due to the observation that car owners exhibit wide variation in involvement. For instance, a person who has minimal involvement with cars may drive a plain model and treat the vehicle essentially as an appliance, whereas another person with high involvement (such as in the case of car enthusiasts) may spend his weekends tinkering with cars and subscribe to several automotive magazines. This potential for variance and the familiarity of the product class to most consumers made automobiles a reasonable choice for scale development efforts.

Psychometric Development

The literature on scaling presents a bewildering array of possible approaches to constructing a multi-item scale. The particular approach employed in this project is that presented by Churchill (1979) in an article on the development of measures for marketing constructs. The sections which follow discuss the steps used in specifying the domain of the construct, generating scale items, measure purification procedures, and the analysis of the scale's structure, as well as the reliability and validity of the final involvement scale.

Specifying the Domain of the Construct

The first step in developing a scale is to specify the domain of the construct under study, based on a review of relevant literature (Churchill 1979). A review of conceptual work on product involvement (e.g., Bogart 1967, Day 1970, Houston and Rothschild 1978, Lastovicka and Gardner 1979, Tyebjee 1979a), indicated the construct has generally been conceptualized in one of two ways. First, involvement has been treated as a temporary concern with high risk products which occurs during the purchase process (Bowen and Chaffee 1974, Houston and Rothschild 1978). Product involvement has also been viewed as a long-term interest in a product which is based on the centrality of the product to important values, needs, or the self-concept (Day 1970, DeBruicker 1979, Houston and Rothschild 1978, Tyebjee 1979a). According to Houston and Rothschild (1978) this second form of involvement is primarily a function of individual differences and as such, is appropriate for present scaling efforts. The temporary or situational form of involvement will not be studied here because it appears to offer little beyond another perspective on perceived risk.

As used in this research, product involvement is a construct which affects consumer behavior on an ongoing basis. Further, involvement varies across individuals, ranging from minimal levels to the extremely high levels exhibited by consumers such as car enthusiasts, wine connoisseurs, or camera buffs. Procedures used to generate scale items appropriate to the above conceptualization of product involvement are discussed in the following section.

Generating Scale Items

In order to achieve content validity for the scale, the item development process was also based on the review of the product involvement literature. In addition, interviews were held with automobile dealers and sports car enthusiasts, persons presumed to be highly interested and involved in cars and therefore, able to shed light on the nature of the construct. As a final source of scale item

ideas, advertising and editorial content of various automotive magazines were reviewed.

This exploratory work resulted in the construction of 66 statements which captured several aspects of involvement noted in the literature. Items dealt with (1) interest in cars (Bogart 1967, Day 1970, Mitchell 1979) and accompanying readiness to talk about cars (Bogart 1967, Corey 1971), (2) the relatedness of cars to important needs or values (Houston and Rothschild 1978, Tyebjee 1979a), and (3) use of one's car to express the self-concept (DeBruicker 1979, Lastovicka and Gardner 1979). Other items which were developed from the experience survey tapped highly product-specific domains such as willingness to perform car maintenance and devotion to the automobile in light of energy and ecological pressures.

The next step in item development involved editing the raw statement set. A group of six judges, consisting of both faculty and doctoral students from the areas of consumer behavior and social psychology, evaluated the 66 items for content validity (i.e., whether or not the items appeared to tap an abiding interest and concern with automobiles). Items which were deemed irrelevant were eliminated along with those which did not produce a consensus as to their direction of scoring. A 44-item preliminary scale emerged from the item development stage.

The scale consisted of items scored according to a six-point Likert-type format. This is the type of scale recommended by Houston and Rothschild (1978) for use in assessing individual differences in product involvement. Responses are scored so that low scores represent high involvement with negatively stated items to be reverse-scored prior to analysis. An individual's scale score is obtained by summing across the items.

This preliminary version of the involvement scale was administered to a group of 381 marketing students in large classroom settings. Classroom administrations were utilized for reasons of convenience and to obtain a nearly perfect response rate. This response rate benefit becomes salient in the case of research on involvement with a single product in that involvement would appear to be a determinant of response. For example, it seems reasonable that individuals highly involved with a product are more likely to complete a mail survey or personal interview that deals with that product than are subjects with low involvement. The responses to the 44-item scale were used in the next phase of scale development, measure purification.

Measure Purification

The major thrust in purifying a multi-item scale is to reduce, as needed, the number of scale items, with the goal of producing an internally-consistent instrument with highly intercorrelated items. This argument is based on the domain sampling model of measurement (Nunnally 1967) which "holds that the purpose of any particular measurement is to estimate the score that would be obtained if all the items in the domain were used" (Churchill 1979, p. 68). When all the items of a scale are highly intercorrelated, it may be concluded that they are drawn from the domain of a single construct.

The most widely accepted indicator of a scale's internal consistency is Cronbach's (1951) coefficient alpha (α) which represents the average of all possible split-half reliability coefficients. Alpha will tend to be large when scale items are highly intercorrelated and thus appear to be tapping the same construct.³

In this phase of scale development, an iterative procedure was followed where alpha was calculated, items with low

³For a fuller discussion of Cronbach's alpha, see Peter 1979.

item-total correlations were discarded, followed by a subsequent alpha calculation. The 44-item preliminary scale produced an alpha of .82. Although this alpha greatly exceeds Nunnally's (1967) criterion for acceptable internal consistency of .50 to .60, further analysis revealed that several scale items had low item-total correlations. A series of alpha calculation iterations produced a set of 17 items which attained an alpha of .83. While this appears to be only a marginal increase in internal consistency, it should be noted that alpha is affected by scale length with more items tending to increase alpha levels (Cronbach 1951, p. 313). For purposes of comparison, the alpha level of the 17-item set was corrected to make it equivalent in length to the 44 item set. Using the formula below, if the 17 item set was lengthened to 44 items while maintaining the same internal consistency, alpha would be .93 (Nunnally 1967, p. 223). This corrected alpha indicates that the

$$\alpha_c = \frac{k \cdot \alpha}{1 + (k-1)\alpha} \quad (1)$$

where: α_c = α corrected for scale length

k = number of times the scale is to be lengthened

α = uncorrected alpha

measure purification process not only produced a more parsimonious set of items, but also one which possesses a significantly higher level of internal consistency. The 17 items along with their item-total correlations are displayed in Table 1.

Scale Structure

Responses to the reduced set of items shown in Table 1 were next used in a principal components analysis to investigate the dimensionality of the scale and shed further insight on the nature of the involvement construct. Although many scale development articles perform principal components or factor analyses at the outset and prior to measure refinement work, Churchill (1979) noted that in such instances, a large number of difficult to define dimensions tend to emerge due to the presence of irrelevant items. It is Churchill's position that principal components analyses are more profitably employed after an internally consistent set of items is obtained via the assessment of coefficient alpha.

In performing the principal components analysis, the eigenvalue ≥ 1.00 criterion was used to limit the number of factors extracted. Table 2 presents the varimax rotated factor loadings matrix. After examining the content of those items with the highest loadings, the six factors which emerged may be interpreted as follows:

Factor 1: Enjoyment of driving and usage of cars

Factor 2: Readiness to talk to others about cars

Factor 3: Interest in car racing activities

Factor 4: Self-expression through one's car

Factor 5: Attachment to one's car

Factor 6: Interest in cars

These dimensions, although specific to automobiles, appear to capture various aspects of product involvement well established in the consumer behavior literature. Factors 1, 4, and 5 capture the centrality orientation of involvement, while Factors 2, 3, and 6 concern product interest. The dimensionality of product involvement originally used to generate the scale items appears to have reasonable empirical support.

TABLE 1
17 Item Involvement Scale

Item Number	Statement	Item-Total Correlation
1.	It is worth the extra cost to drive an attractive and attention-getting car	.344
2.	I prefer to drive a car with a strong personality of its own	.407
3.	I have sometimes imagined being a race driver	.426
4.	Cars offer me relaxation and fun when life's pressures build up	.566
5.	Sometimes I get too wrapped up in my car	.467
*6.	Cars are nothing more than appliances	.395
7.	I generally feel a sentimental attachment to the cars I own	.369
8.	Driving my car is one way I often use to relieve daily pressures	.511
*9.	I do not pay much attention to car advertisements in magazines or on TV	.351
*10.	I get bored when other people talk to me about their cars	.450
*11.	I have little or no interest in car races	.404
12.	Driving along an open stretch of road seems to "recharge" me in body, mind, and spirit	.458
13.	It is natural that young people become interested in cars	.348
14.	When I'm with a friend, we often end up talking about cars	.385
15.	I don't like to think of my car as being ordinary	.449
16.	Driving my car is one of the most satisfying and enjoyable things I do	.530
17.	I enjoy discussing cars with my friends	.519

Reliability Assessment

Although the preceding analyses produced a scale with high internal consistency, Churchill recommends that alpha be calculated on a new sample to assess the scale's internal consistency reliability. Using a new sample of 57 students, responses to the 17-item scale produced an uncorrected alpha of .79. This figure is slightly less than that calculated with the larger sample; however, its magnitude is still well above the .50-.60 level of acceptability, particularly in light of scale length.

Internal consistency reliability, estimated by coefficient alpha, assesses the measurement error which is attributable to scale content. Alpha does not estimate measurement error or unreliability caused by factors which are external to the scale, such as differences in administration situations (Churchill 1979). As a further test of scale

reliability the instrument was readministered to the sample of 57 students after a two week interval. Although the assessment of test-retest reliability is characterized by serious problems brought about by memory and history effects (Nunnally 1967, Peter 1979), this test was used to provide at least some indication of the scale's stability over time.

These two administrations produced a Pearson product moment correlation of .78 ($p < .001$) for summed scale scores. A correlation of this magnitude is evidence of satisfactory test-retest reliability.

Scale Validity

The final stage of the scale development process concerned the initial validation of the involvement scale. Validity deals with the extent to which a scale is measuring what it purports to measure. As Allison (1978) noted,

...for psychological traits, validity is a matter of degree rather than an all-or-none characteristic. Moreover, it must be evaluated over time and various situations, especially in the case of construct validity of a newly developed test (p. 571).

Keeping this in mind, the analyses which follow can only be regarded as providing a beginning in the validation process for the proposed involvement scale.

To assess its criterion validity, the involvement measure was administered to a group of 90 students along with a set of demographic questions and measures of reported behavior. The behavioral measures tapped the frequency of participation in a variety of activities presumed to be associated with high involvement with automobiles. The behavioral items were developed from a review of automotive magazines and depth interviews with members of sports car clubs. Frequency of participation was measured on a six-point scale, ranging from "always" to "never," with lower scores indicative of higher involvement. Frequency of pleasure driving was also investigated using a multichotomous question with six choices ranging from "more than once a week" to "never or almost never." Table 3 presents the correlations of the scale scores and the reported behavioral items. The proposed involvement scale correlated significantly in the hypothesized direction with all of the reported behavioral measures providing evidence of the scale's criterion validity.

Correct nicks and scratches in car's finish with touch-up paint	.239 ($p < .05$)
Perform periodic car maintenance earlier than required by owner's manual	.229 ($p < .05$)
Park away from other cars when in large parking lots to avoid door nicks	.185 ($p < .05$)
	<u>Spearman rho</u>
Take car on pleasure drives	.418 ($p < .001$)

^a n = 90

^b questions tapped frequency of engaging in each behavior

Several researchers have suggested that one measure of a scale's construct validity is whether it can differentiate the positions of groups known to differ on the construct of interest (Churchill 1979, Lundstrom and Lamont 1976). To further validate the scale and determine if it indeed behaves as expected, such an analysis was undertaken.

In order to perform this analysis, the involvement scale was administered to 52 members of sports car clubs. Members of such clubs typically attend ten or more automotive events (e.g., races, rallies, car shows) per year, subscribe to several automotive magazines, and have a considerable financial investment in the ownership of several automobiles. Thus, one can assume these individuals have high enduring involvement with automobiles. The scale was administered at the regular monthly meetings of the car clubs. Scores obtained from the car club members were contrasted with those of the 90 students used in the previous analysis. The student sample was assumed to possess a

moderate degree of interest and involvement in cars relative to the car club members. The mean score for the student sample was 59.01 contrasted with 37.39 (a higher level of involvement) for the car club group. Using a t-test, the difference between the two means was significant at $p < .001$. In addition, significant differences were also found for all the reported behavioral items.

Conclusions

The results presented above indicate that the construct of product involvement is scalable for a particular product class using conventional procedures. Furthermore, the scale presented is a prototype for others which may be constructed for different research applications and it appears to stand up well to traditional psychometric testing procedures. Although the scale presented is applicable only to the product class of automobiles, the product-specificity should not limit its usefulness in efforts to further refine the construct of involvement. The scale would appear to have application to a number of research situations either as a predictor variable or as a covariate. For example, involvement may be related to other consumer behavior concepts such as opinion leadership, perceived risk, innovativeness, brand loyalty, or information processing.

While the above analyses provide preliminary support for the worthiness of the proposed involvement scale, one caution is in order. This scale was developed using student samples, and further testing with other populations and survey modes is needed to further establish the scale's validity.

In summary, this paper has presented a scale to assess individual differences in consumers' involvement with the product class of automobiles as a first attempt to directly scale involvement in a particular product class. Psychometric tests of the measure's reliability and validity seem to provide adequate support that use of the scale in future research deserves consideration.

CONSUMER LEARNING THROUGH EXPERIENCE:
A STUDY AND EXPERIMENTAL PARADIGM¹

Joel Huber, Duke University
Terry Elrod, Columbia University

Abstract

In this study respondents were asked to make a series of choices on a set of stimuli defined by abstract cues. After each choice a reward/penalty was given depending on the quality of the item chosen. Generally, respondents did a poor job of correctly inferring the additive values of the cues from 32 trials. An examination of the patterns of successive choices indicates that respondents were not really attempting to learn but were primarily avoiding negative feedback.

Introduction

The question this paper raises is how well people learn to use unfamiliar cues to guide choice when the only source of information is past choices. In a consumer context a distinction has been drawn between experience goods, whose worth can be ascertained only through consumption, and inspection goods, whose worth can be ascertained prior to purchase (Nelson 1970).

Suppose a consumer desires to discover the most preferred item from a set of unfamiliar experience goods. A rather laborious way to find the optimal product is to try each. Such a process would be more difficult still if feedback from each item had random error since then each brand would have to be sampled a number of times to arrive at a stable estimate of its value. If, however, there is a set of cues that are consistently related to the evaluations of the products, the task of finding the best is simplified. The consumer can sample certain items to determine the worths of the cues and then use the cues to find the most preferred item.

This paper presents a paradigm that allows an exploration of people's use of this latter strategy. It estimates the extent to which they can quickly infer the worths of unfamiliar cues from choice experiences and use these inferences to arrive at better choices. The use of the term "cues" is used rather than "attributes" to emphasize their unfamiliarity and hence the lack of priors as to their worths.

An understanding of how consumers assign worths to cues through experience is important because (1) virtually all cues are of unknown significance to a person at some point in time, and (2) the efficiency of a market economy depends upon the consumer's ability to learn preference through purchasing. Consumers who can't learn to utilize cues efficiently to guide choice need more:

- a) protection by legislation from deceptive, or irrelevant advertising claims;
- b) assistance with brand evaluation by independent testing agencies, and
- c) training in normative methods of comparison that take in-

¹
The authors wish to thank Morris Holbrook and Bob Chestnut for very helpful comments on an earlier draft.

to account the consumer's limited ability to evaluate brands.

Prior Methodology - Multiple Cue Probability Learning

The research tradition that has addressed the question of how well people can learn to use unfamiliar cues to guide choice most directly has been called Multiple Cue Probability Learning (MCPL). Relevant reviews by Slovic, Fischhoff and Lichtenstein (1977) and Schmitt, Coyle and King (1976) provide good overviews of what appears to be a relatively mature area of inquiry. This tradition has (1) controlled stimulus outcome and the relation of cues to choice outcome, (2) measured the subjects' prior beliefs about the cues' relations to choice outcome, (3) studied how rate of learning of cue worth is affected by such factors as the number of different cues, the strength and complexity of their relationship to choice outcome (e.g. nonlinearities, interactions), and the value of different types of additional feedback. A common research paradigm has been to control prior beliefs by presenting abstract stimuli to subjects in an experimental setting. The subject is shown a stimulus-object, (e.g. consisting of three bar graphs of certain heights), then the subject is asked to guess the worth of the stimulus-object, and finally the subject is told its worth (often with some stochastic error). This stimulus/guess/feedback process is repeated 100-400 times. The measure of learning is typically the degree of correspondence between guessed and actual stimulus worths.

While the above paradigm has led to a rich stream of results, it differs in two critical respects from the consumer learning about experience goods referred to earlier. First, in the multiple cue paradigm, notice the subject has no control over the selection of the stimulus object, as s/he might in choosing a soft drink or a detergent. The subject is simply shown the object and asked to assess its worth. Second, in the experimental paradigm the subject is concerned with the accuracy of the judgments rather than the actual worth of the stimulus objects. By contrast, in a consumer trial the worth of the object chosen is important and learning or accuracy may have secondary importance. Thus in consumer choice there is a tension between short term reward and long term information. This tension simply cannot be captured by the traditional multiple cue probability paradigm because choice is passive and the outcome (as opposed to accuracy) is of no material concern to the subject.

A Modified Paradigm

A desire to bring the task characteristics more in line with the consumer context, while still retaining control over cues and outcomes, lead to the development of the following task: (1) allow the subject to choose any one stimulus-object from a set of available ones; (2) inform the subject of the material consequence of the choice made (money won/lost), (3) have the subject repeat this choice/result process 32 times.

Two sets of data were collected. First, the choice/feedback process was administered and monitored by computer, which allowed automatic recording of the subjects' choices, the results of the choices, and the subjects' deliberation times.

Second, the subjects completed questionnaires after finishing the learning task. A first set of questions simply asked respondents to evaluate the 16 possible stimuli on a 7-point quality scale that mirrors the feedback given. A second set of questions asked respondents to directly evaluate each level of the four dichotomous cues.

The 16 stimulus objects are shown in Figure 1, and represent all possible combinations of the four two-level cues: line/no line, large/small, shaded/unshaded, and diamond/square. The name given each stimulus object has a one-to-one correspondence with its geometric configuration, e.g. large corresponds to the suffix 'er' whereas small corresponds to 'ex.'

FIGURE 1
Names and Symbols Used in the Study

Experimental Manipulations

Several factors that have been found in the MCPL literature to affect learning of cue-worths were manipulated.

Relative Importance of the Cues

Respondents in MCPL tasks have been shown to have prior biases with respect to the amount of information in different cues (Dudycha and Naylor 1966, Janke 1972, Castellan 1974).

The current experiment included four levels of dispersion of weights among the cues, ranging from equal importance to highly unequal importance (in which one cue alone accounted for 80% of explainable variance in stimulus worth).

Absolute Worth of Cues

Stated worths of chosen objects contained two error components. First, repetitive selection of the same stimulus yielded different choice outcomes (as in a consumer context, where repeat purchases of a brand do result in different degrees of satisfaction). This source of error is referred to here as 'stimulus error,' and has been found in MCPL tasks to inhibit learning of worths of both stimuli and cues. Second, the cues did not perfectly predict even the expected worth of a stimulus object. This source of error, 'systematic error,' was thought to inhibit the learning of cue, but not object.worth. Each of these sources of error was manipulated as a two-level factor. These manipulations taken together created a 2 (stimulus error) by 2 (systematic error) by 4 (relative cue weights) full factorial design of 16 cells.

The task was performed by 48 MBA students at a major university and typically took 15-20 minutes to complete. These business students were challenged by the task, responding to the experiment as a test of pertinent business-related skills. The 48 respondents allowed three replications per cell. The assignment of weights to cues was rotated across these three replications to give each cue a roughly equal chance, across subjects, of having a given weight.

Results

The main result is that the respondents did not learn the worths of either the stimuli or their cues very well. This result was independent of the experimental manipulations and is based upon analysis of both the questionnaires and the choice process.

Poor Learning as Evidenced by Questionnaires

The measures of learning, as are those in much of the MCPL literature, are based on Brunswik's (1956) lens model as formalized by Dudycha and Naylor (1966). These measures reflect correlations between several estimates of the stimulus worths: (1) Direct estimates were supplied by the questionnaire, (2) Bootstrapped estimates were the predicted worths of the stimuli provided by regressing the direct estimates against the cues, (3) Compositional estimates were derived by combining the ratings of each cue. The implied worth of an object-stimulus was then the sum of the ratings of its cue-levels. Since ratings of the geometric shapes were obtained separately from the ratings of the letters, two separate compositional indices were created.

Given these four subject-based estimates of stimulus-object worths, what measure should be used as a criterion to evaluate the degree of learning reflected in these measures? One could regress each of these measures against the true worths of the stimulus-objects but these true worths are not perfectly related to the cues due to the presence of random error. We therefore calculated a 'fairer' criterion estimate of the stimulus worths by computing those cue weights that would be inferred by a perfect OLS process given the sequence of chosen stimuli and feedback.

These optimal ratings of the stimuli were obtained by regressing the feedback levels against the cue levels scored as dummy variables. The resulting predicted stimulus worths were optimal in the sense of being the best predictors of the particular stimuli chosen. That is, if a respondent concentrated choices among five or six stimuli, the optimal values reflected the fit of the additive model from among these choices. These scores might be quite different from those generated from a broad selection of stimuli. Thus

the optimal scores are relative to the particular choices and to a certain extent control for whether a respondent used a high-learning strategy with many different items chosen or a low-learning strategy. It should also be noted that the optimal values can, in theory, be perfectly reproduced by the subject in that each respondent had the information needed to produce a scale that correlates perfectly with the optimal values.

TABLE 1

Average Correlation of Subject-Based Estimates of Stimulus Worths with "Optimal Estimates"

	<u>Direct</u>	<u>Bootstrapped</u>	<u>Shapes</u>	<u>Letters</u>
Correlation with Optimal	0.19	0.29	0.26	0.31
Standard Error	(0.05)	(0.08)	(0.08)	(0.08)

TABLE 2

Average Correlations Among Subject-Based Estimates of Stimulus Worths

Estimate:	<u>Direct</u>	<u>Bootstrapped</u>	<u>Shapes</u>
<u>Bootstrapped</u>	0.61		
<u>Shapes</u>	0.28	0.43	
<u>Letters</u>	0.34	0.56	0.55

The four subject-based estimates of stimulus worth: direct, bootstrapped, shapes and letters, were correlated with the optimal scales for each individual. The means and standard deviations across the 48 respondents are shown in Table 1. It is noted that, except for the direct estimates, which are predictably unreliable, the three scales correlate about 0.3 with the optimal model. This translates to an R^2 of less than 10%.

The first question raised by this relatively low performance is, how it can be so much lower than typical correlations found in either compositional or decompositional models? The answer to this question can be found by examining the correspondences between the various subjective scales shown in Table 2. These more respectable correlations indicate that consumers are internally consistent. But this internal consistency may greatly overstate actual association with the true worths of the stimuli. Thus it appears that respondents were consistent with their own ratings but these had relatively little correspondence with reality. In the next section we explore the pattern of actual choices made in an attempt to discover the strategies used and why they were unsuccessful in uncovering the true values.

Lack of Learning in Choice Patterns

Some of the reasons for the poor learning become apparent as one examines the patterns of choices through the 32 choice-feedback trials. While no clear criterion of learning is available in this case, one would expect that choices might reflect a partly systematic search for the best stimulus object, and that subsequent choices would be somewhat consistent with information obtained from prior choices.

Lack of Search for Structure

All the stimuli differ from each other on between one and

four cues. By choosing a stimulus that differs from the previous one on only one cue, the change in feedback is an estimate of that cue's worth. We term such switching on only one cue on two consecutive choices an experimental test. The value of such a strategy when there is no error in feedback is clear: by ignoring the cues, all 16 brands must be tried before the best brand is identified, but by correctly inferring an additive relationship between cues and stimulus worth and 'experimentally testing' the cues, only 5 choices are needed to determine the best brand. When feedback contains error, the best brand can never be identified with certainty by either strategy, but even if the subject decides to try all brands in search of the best, trying them in an 'experimental testing' order would yield valuable information. Did respondents in fact employ such a strategy? The answer is no, as is shown by Table 3, which compares the number of cues switched between consecutively chosen stimuli if all stimuli were chosen randomly (and with equal probability) with the frequency observed with our respondents. Note that the percentage of single-switch choices (experimental tests) is virtually identical to that expected under the chance model. This percentage (25%) was unexpectedly small given the high level of information that can be derived from just changing one cue. Instead, most of the switches (30%) involved changing two cues, a strategy that has limited value from an informational standpoint and is only marginally efficient as a way to find a brand that is quite different. High-aversion strategies occurred relatively rarely, perhaps because of the search difficulty in finding the item that differs over three or four of the cues. Not surprisingly, perhaps, zero switches ('brand loyalty') occurred much more frequently than expected by chance. Overall, there is little evidence that respondents acted as "intuitive scientists" by searching for structure using controlled experiments. Furthermore, as the next section shows, even when "experiments" were used their results were ignored.

TABLE 3

Relative Frequency of Number of Cues Switched

<u>Label</u>	<u>Percent of Subjects' Choice Pairs</u>	<u>Percent if Stimuli Were Chosen Randomly</u>
Brand Loyalty (no switch)	23%	6%
Experimental Test (1 attribute switched)	25%*	25%
Experiment/Aversion (2 attributes switched)	30%	38%
Aversion/Experiment (3 attributes switched)	18%	25%
Pure Aversion (all attributes switched)	4%	6%

*Read: Experimental tests, defined as choosing a product with one factor (out of four possible) differing from the previous choice, occurred in 25% of the choice occasions.

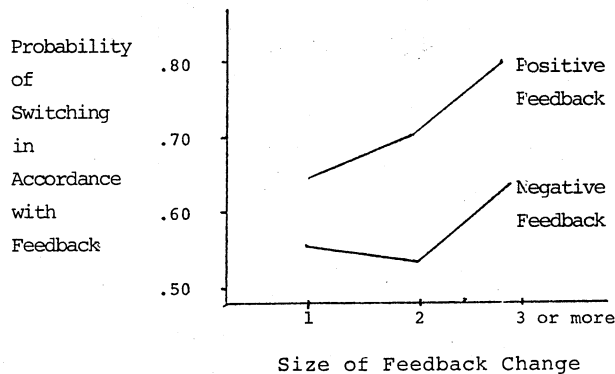

Lack of Response to Structure

Figure 2 shows that, when subjects did switch on only one cue, their next choice often conflicted with the information obtained on that cue. If switching on one cue resulted in a positive improvement in choice outcome, then one might expect the subject to retain that level on the subsequent choice. Subjects in fact did this 65%-78% of the time, depending upon the magnitude of the change in outcome. If switching a cue resulted in a negative change in choice outcome, then one would expect subjects to switch

back to the original one on their subsequent choice; they in fact did so less than two-thirds of the time.

FIGURE 2

Reactions to Positive and Negative Changes in Feedback When Exactly One Cue is Changed (Experimental Test)

Evidence of Sensitivity to Immediate Feedback

What, if anything, did influence the number of cues switched on consecutive choices? There are three likely candidates. First might be the outcome on the last item chosen--the higher its value, the greater the probability that the next choice will be highly similar. Another possibility is the change in outcome for the last two choices. One would expect smaller change following an increase in choice outcome than following a decrease. Finally, one might expect experience to result in switching on fewer cues; that is, the respondent might, with experience, eliminate some stimuli from consideration.

In the present study, current feedback accounted for virtually all of the accountable variance in the number of cues switched. Thus, once current feedback is accounted for, the change in feedback was not significant and task experience became much less so. The effect of current feedback is shown in Figure 3.

Summary and Directions for Future Research

The foregoing has described an experimental paradigm that modifies the multiple cue probability learning task to better approximate that aspect of consumer learning that occurs through the experience of the product. Different ways were tried to get respondents to give the values of cues that correspond to the feedback received on the 32 purchase/feedback occasions. While these different measures had reasonable correlations among themselves (internal validity), none accounted for more than 10% of the variance (external validity) that could have been realized had the respondents been OLS processors. The patterns of choices provided some explanation for the lack of apparent learning in the task. Respondents did not use what would have been the most efficient way to measure cues worths, experimental tests, any more than would be expected with random selection of stimuli. Further, where experimental tests did occur, subsequent choice was in accordance with the feedback from the

FIGURE 3

Effect of Current Feedback on the Number of Cues Switched on Next Choice

test in only 2/3 of the cases. Indeed, the best predictor of the number of cues switched was simply the value of the last time chosen--the more negative its feedback, the more dissimilar the next item chosen. Perhaps so little learning occurred because respondents were not trying to learn but simply avoiding bad products, a kind of aversive random walk.

While the results from this exploratory study are too tentative to be applied directly to consumer learning in the marketplace, the importance of learning in that context is great enough to warrant research into the following questions:

Can Subjects Be Induced to Learn Cue Worths?

Several factors would likely serve to increase the level of cue learning. First, the number of stimuli can be increased relative to the number of cues, thus forcing attention to cues rather than global judgments on stimuli. Second, the consequences of choice can be increased. This change would increase the cost of a 'try all brands and see' strategy. Finally, more cue learning might occur with messages (e.g. ads) to orient respondents to the different cues.

Does Prior Knowledge Affect Learning?

Abstract choice objects were employed in this study, as in the MCPL literature, to minimize the effects of prior learning and, most importantly, to control choice outcomes. An alternative might be to use hypothetical brands of a real product class (as in conjoint analysis), measure (rather than control) the subjects' priors concerning cue worths, and then study the change in these priors as a result of feedback on choices. Alternatively, one might use brand names and measure prior beliefs concerning both cue (attribute) and brand worths.

Thus, the current study, while tentative and largely exploratory, suggests that consumers may have difficulty in correctly inferring the values of purchase cues from product experience. It is hoped that future research will shed more light on this issue of concern to regulators, practitioners and consumer researchers.

MEASURING CONSUMER ATTITUDES TOWARD ALTERNATIVE CHECK VERIFICATION SYSTEMS

David J. Barnaby, University of Tennessee
John W. Philpot, University of Tennessee
Richard C. Reizenstein, University of Tennessee

Abstract

While the technologies for various electronic funds transfer (EFT) systems are well developed, little attention has been directed toward the study of consumer attitudes toward and acceptance of these technologies. In particular, several check verification systems (CVS) have been introduced as an electronic mechanism to verify consumer checks and reduce the number of bad checks accepted by merchants. Since the systems provide unique benefits to different consumer and merchant user groups, an assessment of consumer reaction to CVS alternatives provides insights into consumer check cashing attitudes, activities, and preferences. Multivariate procedures are utilized to yield profiles of specific CVS preference groups.

Introduction

Relative to other consumer oriented service industries, banking has only recently begun to devote substantive attention to the application of established marketing principles. Certain financial institutions, such as City National Bank of Columbus (Ohio), have emerged as innovators in their use of such practices to develop new market segments and to better serve their existing customers. The banking industry as a whole, however, is only beginning to tap the marketing resources available to them to better assess market reaction to and promote the potential array of consumer services available under the umbrella of Electronic Funds Transfer Systems (White and Woodside 1973).

Historically, the primary thrust in what many banks have perceived as marketing, both overall and with respect to Electronic Funds Transfer Systems (EFTS), has been institutional and product-oriented, rather than market oriented (Mason and Mayer 1974). Bank marketing has historically been narrowly defined, as sales and/or promotion in the rare instances where it has been used, as opposed to the broader strategic approach emerging in other consumer-oriented industries (White and Woodside 1973). This direction is evident in the numerous articles that have appeared in the last few years which discuss the concept of EFTS as well as specific EFTS applications (Automated Teller Machines, Point of Sale Systems, Check Guarantee Systems, etc.). These generally dwell on the advantages and disadvantages of EFTS (more from the financial institution's perspective than that of the consumer or retail merchant), and costs versus benefits with relatively little emphasis on market planning, market acceptance, consumer research, or promotion to the consumer or retail sectors of either the EFTS concept or the potential variety of EFTS services (Benton 1977).

In light of the evident paucity of marketing-oriented consumer research in this field, this study will attempt to apply marketing research and analytical techniques to a specific type of EFTS: check guarantee/verification systems (CVS), systems which identify bad check writers by use of a computerized negative card file accessible via retail in-store terminals. The major objective of this research will be to apply the market segmentation concept to describe and classify potential consumer preferences for two general categories of check verification systems: consumer operated and retail employee operated.

Literature Review

As stated, the preponderance of literature related to consumer attitudes toward and usage of EFTS has focused on the advantages, disadvantages, costs, and benefits of EFTS, various delivery mechanisms, and the variety of services available under the EFT umbrella. Business Week, Fortune, and Harvard Business Review, among the general business periodicals, have featured such articles in recent years ("Electronic Banking: A Retreat from the Cashless Society" 1977, Rose 1977, Benton 1977), in addition to such financially oriented publications as The Banker, Banker's Monthly Magazine, the Journal of Bank Research, and Savings and Loan News (Simon 1977, Nadler 1977, White and Woodside 1973, "You Can Take the 'E' out of EFT" 1977). Moreover, with the experimental implementation of various forms of EFTS services in the banking community, successes and failures are increasingly reported, including the generally favorable experiences of City National Bank of Columbus and the Wilmington Savings Fund Plan as well as the less successful experiment at Glendale Federal Savings and Loan ("Electronic Banking: A Retreat from the Cashless Society" 1977, De Costa 1977).

In contrast to these are articles directed toward the application of marketing to bank services other than EFT (Levy 1973). Some of these studies attempt to apply retail marketing techniques in a segmentation context, generally describing users and nonusers of types of banks or banking services, such as commercial banks (as opposed to savings and loan institutions), bank credit cards in terms of life styles, and overdraft checking in terms of usage rates (Arbeit and Sawyer 1974, Plummer 1971, Morgan 1978). Most of the remaining marketing research in the field tends to emphasize specific kinds of analyses such as determinant attribute analysis and perceptual mapping as segmentation mechanisms (Anderson, Cox, and Fulcher 1976, Gillette and Evans 1974). Marketing-oriented research on specific EFT services has been reported only rarely, with the Vinson and McVandon study of the impact of consumer education on attitudes toward the debit card concept one of the only recent examples in the marketing literature (Vinson and McVandon 1978).

Research Methodology

During 1979, a personal interview survey of 325 consumers was conducted by means of a systematic random sample from the City Directory of a medium-sized Southeastern city (population 200,000). The primary objective of this research was to assess consumer familiarity with and attitudes toward the concept of EFTS, as well as specific EFT services; the major thrust of the research, however, was launched toward alternative forms of check guarantee/verification systems (CVS). (Coincidentally, CVS were initially introduced in the community shortly after completion of the study.) Because of respondents' potential unfamiliarity with point of sale/check verification systems (and their variations), focus groups were utilized to get an idea of the level of consumer and retailer knowledge in this field and to pinpoint possible areas for investigation. The check verification systems under study, in many cases, represented entirely new services that would be potentially available in the market areas; hence, the focus groups were followed by extensive personal interviews with respondents over a

four-month period to gauge consumer reaction to this new EFT concept.

In order to focus the information collection on the most relevant subset of the sample, i.e., those who write checks outside the home who would be the critical consumer market for check verification systems, two filter questions were posed: Respondents were first asked if they had checking accounts; of those interviewed, 21% (or 68) did not. Interviews with these individuals were terminated after collection of demographic data. Subjects who did have checking accounts were then queried as to whether they used checks for purposes other than bill paying at home; 20% (or 51) did not, and were eliminated from the remainder of the interview after classificatory information was obtained.

The remaining 206 respondents were first analyzed in comparison with updated census data, adjusted for inflation by use of the Consumer Price Index. This information, provided in Table 1, shows an excellent match in the age, income, and marital status categories between the sample and updated Census figures for the SMSA. (In the age category, children under 18 were removed from the Census figures and the remaining totals readjusted, as children did not qualify as potential respondents.) Given the close parallel in most categories between the sample and the Census data, it would seem as if the respondents are potentially representative of the market area under study.

TABLE 1
DEMOGRAPHIC PROFILE OF RESPONDENTS
COMPARED WITH CENSUS DATA
(N = 260)

Demographic Category	Respondent (%)	SMSA (Census %)
<u>Age:</u>		
Under 20	1	1
20-29	26	24
30-39	23	18
40-49	18	19
50-59	15	17
60 and over	18	21
<u>Income:</u>		
Less than \$10,000	20	20
\$10,000 - \$19,999	39	40
\$20,000 - \$29,999	25	24
\$30,000 and over	16	16
<u>Occupation^a:</u>		
Retired	13	N.A.
Professional/Technical	26	17
Manager/Proprietor	12	8
Blue Collar	22	33
Sales	7	8
<u>Sex^a:</u>		
Male	74	47
Female	26	53
<u>Marital Status:</u>		
Married	67	65

^aThe major check writer in the household was the subject of the interview, accounting for much of the variation of the sample from Census figures.

Results

Of the 206 questionnaires from respondents who completed the full forty-minute personal interview, 11 could not be utilized due to missing data; less than half of the remaining 195 had ever heard of point of sale (POS) or check verification systems. In fact, only 2% had ever used a POS

terminal. These low percentages correspond to the limited development of electronic funds transfer systems of any type in the relevant market area. Despite this lack of familiarity with EFTS, a majority of respondents were clearly interested in check verification systems that would both aid in the processing of checking payments and speed transactions. Consumers noted that of their total check cashing activities, nearly 45% required some form of check verification procedure. These transactions normally occurred in the following types of retail establishments (in decreasing order of frequency): grocery stores, department stores, drug stores, discount stores, and auto service stores. Given such results indicating a generally low level of awareness, but a strong interest in check verification systems, consumers' attitudes toward specific check cashing activities will be explored in depth in the analyses to follow.

Initial assessment of consumers' attitudes toward check cashing activities were measured by 27 Likert scale items developed from focus group research. While these questions included items that pertained to many aspects of payment for retail goods and services, a number of items were specific to check verification procedures and systems currently employed by merchants. In Table 2, a sampling of these items, representing greatest percentage agreement or disagreement, is shown along with the agreement or disagreement scaled percentage. Generally, the sample "agrees" that bad checks are a problem for retailers and empathizes with merchants regarding this problem. Respondents, however, found charge cards to be more acceptable than checks to merchants and strongly preferred charge card verification systems to present check cashing systems. (From the merchant perspective, a verification system that substantially shifts risk of nonpayment for goods or services to the credit card sponsor is preferable.) Consumers do agree substantially that retailers should cash checks, and should provide an efficient identification procedure that would provide both protection for the merchant and a nonthreatening or embarrassing transaction environment for the consumer. Interestingly, driver's license numbers are assuming an increasingly critical role in this identification procedure.

TABLE 2
CONSUMER ATTITUDES TOWARD CHECK CASHING
(N = 195)

Percentage Agreement	Attitudinal Item
55%	I prefer to pay for retail purchases by check.
43%	I would rather use a charge card for retail purchases.
78%	I do not like to carry much cash with me.
72%	Retailers should cash personal checks.
66%	Merchants are eager to accept my personal check.
73%	It is difficult to get a check cashed without a driver's license.
68%	I prefer to patronize retailers where I am known, since no ID is required for personal checks.
52%	I prefer retailers' credit card verification procedures to check cashing procedures.
86%	Bad checks are a major problem for retailers.
86%	Retailers require a lot of ID to cash checks because of bad check problems.
84%	Charge cards are more acceptable to merchants than personal checks.
Percentage Disagreement	Attitudinal Item
91%	I don't really care if merchants get stuck with bad checks.
59%	I resent a retailer who requires an ID so I can purchase.
52%	Retail check cashing procedures make me feel untrustworthy.
49%	It is embarrassing to be required to have so much ID to get my check cashed in a retail store.
66%	I have never written a check that was returned for insufficient funds.

Table 3 indicates CVS attributes deemed most important by consumers in evaluating alternative systems for check verification. These results depict consumers as stressing the importance of such status quo factors as price maintenance, account privacy, system reliability, stop payment procedures, "float" availability, and remedies for accidental overdraft. Additionally, such factors as bad debt reduction, faster identification procedures, cashing other than personal checks, and cashing checks for more than the amount of purchase are considered important components of the system.

TABLE 3

IMPORTANCE OF CHECK VERIFICATION SYSTEM ATTRIBUTES
(N = 195)

Respondents Rating as Important (%)	System Attributes
95	Mechanically reliable system.
94	No increase in retail prices with system use.
93	Guarantee of customer privacy regarding account balance.
91	Fewer bad debts for merchants.
90	Faster identification procedures for check cashing.
89	Ability to stop payment on checks.
87	Ability to remedy accidental overdraft.
75	Ability to cash checks other than personal checks.
72	Ability to cash checks for more than amount of purchase.
62	Ability to cash checks without identification.
59	System operated by consumer.
52	Ability to continue use of "float."

Prior to testing the relationship between consumer attitudes toward check cashing activities, importance ratings of attributes, and specific check verification systems, factor analyses of the set of 27 attitudinal items and the 29 importance ratings were conducted. Results of both of these analyses were quite lackluster with communalities and factor loadings being very low; interpretation of the factors proved difficult. Attempts to correlate factors with system preferences proved nonsignificant at the .05 level. These poor results imply, in part, that consumers appeared to display some confusion about CVS systems due, to a great extent, to their unfamiliarity with these systems; as a result, they showed little consistency in their replies to the items.

As an example, consumers expressed a strong preference for small retailers who knew them and could accept checks without ID; at the same time they reported no resentment of retailers requiring ID. Both items had high positive loadings on one of the attitude factors, yet the first item was positively correlated with the grouping variable and the second item had a negative correlation with the grouping variable. This led to a factor that was practically orthogonal to the grouping variable.

The diffuse nature of the factor analysis, which implies confusion in the minds of consumers about CVS, suggests that subsequent discriminant analysis results would be subject to change, particularly after a public education and information campaign. That is, the real polarization of preferences has yet to occur.

In a further effort to identify those variables related to specific CVS preferences, correlations between the larger predictor sets (attitudes, attribute importance, and demographics) and consumer operated system preferences were obtained. Those items significant at the .05 level (univariate) or better are shown in Table 4 and were selected as candidates for further study. (To preclude spurious correlation, these and subsequent tests were made using the critical value that is appropriate when all predictors are

included in the analysis, i.e., $F .05 (1,98) = 3.94$.) In total, 13 candidate variables survived this correlational screening, 10 of which were equally divided between attitudinal and importance items. Only one item each pertaining to specialty store system usage intentions, friends as a new product information source, and number of children and/or others 15 years or older living at home, comprised the final three candidates. All correlations, as shown in Table 4, were less than .20, reinforcing the relatively weak level of the relationships discovered.

TABLE 4

CORRELATIONS OF SIGNIFICANT VARIABLES WITH
CONSUMER CVS PREFERENCE

Variable	Correlation	Significance Level
I waste a lot of time waiting for merchants to cash my checks.	.133	.03
I prefer to patronize small retailers because they will accept my check without identification.	.155	.01
Retailers should accept personal checks for amount of purchase.	-.170	.01
If it were not so difficult I would consider changing banks.	-.122	.04
I am extremely satisfied with the bank in which I have my checking account.	.157	.01
Faster than normal identification procedure for check cashing is important.	.183	.01
System operated by sales clerk (instead of customer) is important.	-.114	.05
Ability to obtain cash readily in retail stores is important.	.114	.05
Ability to stop payment on approved checks is important.	.177	.05
Ability to cash nonpersonal checks (e.g., payroll, social security) in addition to personal checks is important.	.124	.04
Likely to use system if available in specialty stores.	.115	.05
Friends as important new product information source.	----	----
No. of children/others 15 or older that reside in household.	-.156	.01

Despite the weak (though significant) nature of the correlations, however, the candidate variables were included as predictors in a multiple discriminant analysis to test the ability of this multivariate function to discriminate between those consumers preferring consumer as opposed to retail employee operated check verification systems. Preference grouping for either the consumer operated check verification system or the retail employee operated check verification system were determined by categorizing preferences for specific CVS alternatives. Scenarios describing the use and function of each alternative were provided to familiarize respondents with each CVS possibility prior to measurement of consumer preferences. First choice preference served as an indicator of preference for consumer versus employee operated CVS; respondents were grouped accordingly with the great majority (73%) favoring the consumer operated version.

The results of the stepwise MDA shown in Table 5, reveal those predictors which significantly ($p = .01$) discriminate between consumer and employee operated CVS preference groups. Examination of the results (means and standardized discriminant coefficients) suggests that those respondents preferring consumer operated check verification systems can

be described as: consistently agreeing that retailers should cash personal checks for the amount of purchase, extremely satisfied with the bank handling their checking account, desiring faster than normal identification procedures for check cashing, having few children or others 15 years or older residing in the household, and counting friends as an important new product information source. Correspondingly, those respondents preferring retail employee operated check verification systems agree to a lesser extent that retailers should cash checks for amount of purchase, are less well satisfied with their bank, have a lesser desire for faster check cashing identification procedures, have barely any children or others 15 years or older residing in the household, and do not rely as much on friends as a new product information source.

TABLE 5
DISCRIMINANT ANALYSIS--CONSUMER VS. RETAILER
OPERATED CVS PREFERENCE GROUPS

Variable	Means (Std. Deviations)		Standardized Discriminant Coefficients
	Consumer CVS Preferred	Retailer CVS Preferred	
Cashing personal checks for amount of purchase is service retailers should provide.	2.00 (1.19)	1.57 (.83)	.532
I am extremely satisfied with the bank in which I have my checking account.	1.62 (.97)	2.02 (1.27)	-.426
Faster than normal identification procedure for check cashing desirable.	1.40 (.65)	1.69 (.86)	-.434
Number of children/other 15 or older that reside in household.	.70 (.96)	.33 (.68)	.406
Friends as important new product information source.	1.58 (.69)	1.90 (1.06)	-.379

A further indication of the ability of the discriminant function to statistically classify respondents based on the five significant predictors is found in the hit or miss classification results presented in Table 6. The disproportionate group sizes precluded the traditional hold-out sample analysis to test the classificatory ability of the discriminant function. The jackknife procedure was utilized to test the function, however, with results showing a 75% correct classification rate while chance classification was calculated at 61%.

TABLE 6
CLASSIFICATION OF CONSUMER VS. RETAILER
CVS SYSTEMS USING MDA^{a,b}

Actual Group	No. of Cases	Predicted	Predicted
		Consumer CVS Preferred	Retailer CVS Preferred
Consumer CVS Preferred	143	132 (92%)	11 (8%)
Retailer CVS Preferred	52	37 (71%)	15 (29%)
	195		

^aPercent of cases classified by chance: 61%.

^bPercent of cases classified by MDA: 75%.

Conclusions and Implications

From reviewing the literature, it seems evident that the cashless/checkless society and electronic funds transfer

systems (EFTS) are only in the early stages of market development. The issues and controversy surrounding EFTS has had primarily a financial and product-oriented focus, rather than a marketing-oriented perspective. Some departure from this product orientation, however, can be found in the stances of consumer groups advocating the limited adoption of EFTS because of its potentially negative impact on consumer privacy. Otherwise, EFTS innovations such as check guarantee/verification systems have received relatively little attention in what little marketing-directed financial literature exists, a major omission since transaction volume is a key variable in estimating the potential profitability of such systems, thus emphasizing the importance of marketing techniques to achieve necessary volume levels.

Check verification systems (CVS) unquestionably address a potential need evident in retail transactions. Checks continue to play a key transactional role; consequently, bad checks pose significant problems for both retailers and consumers. CVS is an EFTS alternative which has the potential to dramatically reduce bad check losses, if sufficient retailers and consumers will use such systems to make them profitable to sponsoring banks or business firms.

Since several CVS alternatives exist, research is desirable to gain insight into consumer preferences for specific CVS options and alternatives. The personal interview survey conducted in this study attempted to provide at least a partial response to this issue. Although geographically limited, and thus not generalizable to a national market, the results do provide insight into the differentiating characteristics of two distinct CVS alternative preference segments in a retail market prior the actual introduction of such systems.

Data collected by this research showed that, for the market area under examination, consumers as well as retailers definitely recognized the problems associated with bad checks. Impact on retailer costs and thus prices were understood by a large majority of respondents; the reasons for identification procedures to minimize such expenses were thus comprehended, although disliked due to their inconvenience and time consuming nature, by consumer subjects. Despite such perceived negative aspects of retail check cashing, however, availability of retail check cashing, at least for the amount of purchase, was a highly desired service in retail stores. CVS alternatives were seen as quite attractive to many respondents desiring such check cashing availability, due to the simpler and faster identification procedures inherent in the consumer operated system in particular.

Results of multiple discriminant analysis of preference for consumer versus retail employee operated CVS support several differentiating characteristics of groups favoring each type of alternative, including the greater orientation of those preferring the consumer operated system toward more check cashing and faster identification procedures. In addition, a potentially useful promotional idea for such systems is revealed in the MDA results. The greater reliance on friends as an important new product information source by those respondents favoring consumer operated CVS is an important insight for those interested in marketing such techniques. If this CVS method was launched as a new product introduction, apparently word of mouth could play a key role; thus, consideration of ad copy using a representative of friends' dialogue might be effective as a promotional mechanism.

Finally, the MDA results show that those who appear to rely more on credit cards and favor credit card transaction procedures also appear to be more interested in retail employee operated systems which parallel credit card verification procedures. On the other hand, the group favoring the consumer operated CVS seems to rely more on check payment for retail purchases and sees this self-initiated and self-operated system as preferable.

DISCUSSION
INVOLVEMENT, LEARNING AND ATTITUDES

David M. Gardner, University of Illinois, Urbana/Champaign

These three papers are a good example of the diversity in consumer research that exists today. The Huber and Elrod study is aimed at theory development using non-consumer stimuli. Block's paper represents an attempt to point out a missing tool in the involvement research field and develops a specific measuring tool. And different yet is the Barnaby, Philpot and Reizenstein paper that is very much an applied attitude study.

It is encouraging to see research of the type presented by Huber and Elrod. Any discipline can benefit by theory development research. Our tendency in consumer behavior is to "borrow" and therefore we often avoid some of the basic steps in theory development. Therefore, an attempt to understand choice, unencumbered by any previous experience or learning is welcome. Unfortunately, the writeup of this effort leaves out a discussion of many of the critical details that should allow others to evaluate the design and results of the study. This may be a very worthwhile study that will serve as the basis for other research, but, it is almost impossible to determine from the writeup. For instance, the authors do not specify what the seven-point quality scale was measuring (i.e., the direct measure). Also, it is not at all clear how the dependent variables were measured. The manipulation of systematic error seems questionable as many cues (attributes) predict expected worth of value. Without knowing the rationale for using only 32 trials (in another place 48 trials were specified) it seems that the results of this experiment might be very different if subjects were given more trials.

In addition to including a larger number of trials, this study would have been more useful if it had been replicated in four versions. The first replication would have been without any manipulation of either stimulus or systematic error. The second and third replications would have included one of these error manipulations. The fourth replication would have included both. In its present form, only the fourth replication has been attempted. Therefore, the effect of the manipulations are confounded and make interpretation difficult.

The reaction to Block's paper dealing with involvement with automobiles is almost certain to be mixed. On the one hand, the author is to be commended for the compact and relevant review of the literature and for the design and execution of the study. But, on the other hand, one must question the rationale for the study and ask--why do we need one more involvement scale.

In many ways, this study is a straightforward application of the standard methodology for scale development and testing. Unfortunately, there is little concrete support for asserting that the scale measures "involvement." If in fact, Block does want to build on existing work, then it is important to carefully link one's work to existing work. Therefore, a potential and serious flaw in the study is the lack of statistical correlation with other measures of involvement. It seems important to determine, if in fact, this new scale truly contributes any additional insight into our understanding of involvement. Specifically, does this new scale differentiate better than the Lastovicka and Gardner scale or even a simple question like, "How much do you care about cars" or "How important are cars to you?"

In addition, Block seems to overlook the difference between scales that measure differential involvement between consumers for a particular and specific product class and scales that measure differential involvement for an individual consumer toward different products. The study presented here deals only with the former. A brief procedural note is the seeming lack of evidence that criterion validity is adequately assessed. Pre-tests are not reported.

The Barnaby, Philpot and Reizenstein study is a relatively straightforward, practical, management oriented study. It is not exciting, and does not develop any new frontiers. Its analysis is not sophisticated nor the results particularly startling, although they may be useful as a management tool.

Two observations seem appropriate, however. First, no organizing or conceptual framework for this study is specified or evident. Therefore, it is not completely clear why the exact attitudes, attributes or demographics specified should correlate with CVS preferences. Future investigators who will look at this study for direction, may go away empty handed if they desire to learn what predicts CVS preferences from a conceptual perspective.

Second, the authors do not seem to take advantage of the "involvement" literature mentioned in the Block study. CVS is most likely a higher involving activity, at least initially. Therefore, this would suggest an analysis to sort out variables that would be more apt to predict initial behavior toward CVS based on high involvement issues.

TESTING COMPARISON LEVEL AND PREDICTIVE
EXPECTATIONS MODELS OF SATISFACTION

John E. Swan, University of Alabama in Birmingham
Warren S. Martin, University of Alabama in Birmingham

Abstract

Based on past literature and current developments in the field of consumer satisfaction, models were developed relating to the prediction of satisfaction from initial levels of expectations, disconfirmation of expectations and disconfirmations of past experience on similar products. In order to test these propositions, 8 different regression models were created. Data from 67 student subjects relating to the satisfaction of an automobile were analyzed. The disconfirmation of past performance expectations and initial expectations were the strongest predictors of satisfaction with an adjusted R^2 of .47.

Introduction

This paper briefly reviews the comparison level theory of satisfaction proposed by LaTour and Peat (1979b) and reports an empirical test of this theory along with empirical tests of other models of satisfaction. While the comparison level theory of satisfaction has intuitive appeal it has only been subject to a single empirical test (LaTour and Peat 1980, 1979a). A secondary purpose of this paper is to compare the LaTour and Peat model to other models in terms of their ability to explain satisfaction. In particular the contributions of the disconfirmation of predictive expectations and initial level of expectations as predictors of satisfaction were tested.

Models of Satisfaction

Most of the recent models of satisfaction have been oriented towards a paradigm relating initial expectations to perceived performance of the product (or service) (Day 1977). The main proposition is that satisfaction is directly related to the disconfirmation of expectations (Oliver 1977, 1979, Howard and Sheth 1969, Swan 1977). Disconfirmation is a process in which the user subjectively compares post purchase product performance to prior expectations. Positive disconfirmation results if post purchase performance exceeds expectations. Confirmation occurs if performance equals expectations and negative disconfirmation results if performance is short of expectations. Disconfirmation has been conceptualized as continuous variables that can range from a high positive value (as performance exceeds expectations) to a low or zero value (as performance approaches and equals expectations) to a high negative value (as performance decreases relative to expectations (Oliver 1979, 1977; Swan 1977). Satisfaction has also been thought of as a continuous variable that can range from high satisfaction to indifference to dissatisfaction and will be hereafter referred to as "satisfaction" (Day 1977). It should be noted that researchers have not claimed that interval levels of measurement have been achieved for disconfirmation and satisfaction. In addition, whether satisfaction is a continuous variable or whether satisfaction and dissatisfaction are two different states is a point that has not been fully resolved (Leavitt 1977). The main prediction of the Day model, that satisfaction is directly related to disconfirmation has been supported by research findings (Swan 1977; Oliver 1979, 1977; Swan and Combs 1976).

LaTour and Peat (1979b) have discussed the basic disconfirmation of expectations model along with similar ap-

proaches. They have critically evaluated much of the past work in this area and offered an alternative conceptualization of consumer satisfaction. LaTour and Peat's basic approach is that satisfaction is a function of how well a product performs on a set of attributes and for each attribute the customer compares performance to a comparison level (Thibaut and Kelly 1959). Favorable performance in relation to the comparison level for an attribute would contribute to satisfaction due to a positive disconfirmation of expectations.

The important theoretical contribution of the comparison level approach is that three possible sources are identified as forming the comparison level: (1) past experience with different levels of the attribute for similar products used for similar purposes; (2) levels of the attribute that the customer believes similar customers have received; and (3) expectations from information provided by marketers or the expected attribute level based on unique characteristics of the specific purchase situation.

As an example, an automobile owner's satisfaction with the attribute miles per gallon (MPG) achieved with a new car would be related to the difference between the obtained MPG compared to the mileage of his previous car, the mileage his friends claim for their cars, and manufacturers, dealer, and EPA mileage estimates. Overall satisfaction is predicted to be a function of the difference between obtained performance compared to the comparison level which is composed of the three sources of performance standards, past experience, experience of others, and the present situation.

Hypotheses and Models Tested in this Study

As noted above, prior research has found that satisfaction is directly related to disconfirmation. Implicitly the literature has defined expectations as predictive expectations. Miller (1977a) as well as Summers and Granbois (1977) have argued that consumers may have different kinds of expectations including what Summers and Granbois (1977) have termed predictive expectations. Predictive expectations have been thought of as preusage anticipations of how well the product will perform (Swan and Trawick 1979). The first model in this study tested the hypothesis that:

H1: Satisfaction will be directly related to the disconfirmation of predictive expectations.

Disconfirmation was measured as the after usage attribute ratings of the test product (A_i) minus predictive expectations ($PRED_i$) summed across 12 attributes. The model used to test the first satisfaction (S) hypothesis was:

$$\text{Model I. } S = \sum_{i=1}^n (A_i - PRED_i) \quad (1)$$

The set of hypotheses tested included some basic ones plus the same hypotheses with an expectation term added because Oliver (1979, 1977) and Swan (1977) have found that expectations explained some variation in satisfaction above the attributable to disconfirmation of expectations. Expectations may be related to satisfaction due to a level of performance effect. The argument is as follows. Expectations indicate how well or poorly the user anticipates the product will perform. Assume that in two cases performance

matches expectations. In the first case expectations and satisfaction were both at a high level, the users should be satisfied. In the second case both expectations and performance were low, so user satisfaction should be low. Swan and Trawick (1979) have found that performance meeting high expectations results in higher satisfaction than performance equal to low expectations. The second hypothesis and model was:

H2: Satisfaction will be directly related to both predictive expectation (EXP) and disconfirmation of predictive expectations.

$$\text{Model II: } S = \text{EXP} + \sum_{i=1}^n (A_i - \text{PRED}_i) \quad (2)$$

The full LaTour and Peat theory explains satisfaction as follows:

$$S = \sum_{i=1}^n (A_i - W_1 \text{PRED}_i - W_2 \text{PAST}_i - W_3 R_i). \quad (3)$$

Where S = satisfaction; A_i = after usage subjectively experienced attribute level; PRED_i = the expected value of the attribute level based on the characteristics of the particular situation; PAST_i = past experience with attribute levels for similar products; R_i = attribute levels experience by reference persons; n = number of salient attributes; $W_1 W_2 W_3$ = empirically derived weights. Due to some limitations that will be explained more fully below, this study was not designed to test the LaTour and Peat model so that a reduced form of the LaTour and Peat model was tested:

$$S = \sum_{i=1}^n (A_i - \text{PRED}_i - \text{PAST}_i) \quad (4)$$

The PRED_i and PAST_i terms constitute the comparison level, the third hypothesis combined with this model was:

H3: Satisfaction will be directly related to perceived product performance (A_i) minus the comparison level ($\text{PRED}_i - \text{PAST}_i$).

$$\text{Model III: } S = \sum_{i=1}^n (A_i - \text{PRED}_i - \text{PAST}_i) \quad (5)$$

The fourth hypothesis added expectation as an independent variable:

H4: Satisfaction will be directly related to expectation and perceived product performance minus the comparison level.

$$\text{Model IV: } S = \text{EXP} + \sum_{i=1}^n (A_i - \text{PRED} - \text{PAST}_i) \quad (6)$$

The LaTour and Peat approach raises the interesting possibility that satisfaction may be related in some way to the disconfirmation of both past performance and predictive expectations. How the variables should be related is not clear from the literature. Because satisfaction theory and research is in its formative stages, we felt that it would be useful to test for relationships between satisfaction and disconfirmation of past performance (hereafter disconfirmation-past) and predictive expectations (hereafter disconfirmation-predictive) including and excluding an expectation term as variations in the LaTour and Peat framework.

The following hypotheses and models were analyzed:

H5: Satisfaction is directly related to disconfirmation-past performance expectations.

$$\text{Model V: } S = \sum_{i=1}^n (A_i - \text{PAST}_i) \quad (7)$$

H6: Satisfaction is directly related to expectation and disconfirmation past performance expectations.

$$\text{Model VI: } S = \text{EXP} + \sum_{i=1}^n (A_i - \text{PAST}_i) \quad (8)$$

The seventh hypothesis analyzed satisfaction as a function of the disconfirmation of both past performance and predictive expectations and the eighth model included the expectation term:

H7: Satisfaction is directly related to disconfirmation of past performance and predictive expectations:

$$\text{Model VII: } S = \sum_{i=1}^n (A_i - \text{PAST}_i) + \sum_{i=1}^n (A_i - \text{PRED}) \quad (9)$$

$$\text{Model VIII: } S = \text{EXP} + \sum_{i=1}^n (A_i - \text{PAST}_i) + \sum_{i=1}^n (A_i - \text{PRED}) \quad (10)$$

Method

Design of the Study

The design of the study was a longitudinal approach where expectations (PRED_i , PAST_i , EXP) were measured prior to a test drive of a Pinto automobile and after the test drive ratings of perceived performance (A_i) and satisfaction (S) were obtained. The 67 subjects were all students in basic marketing classes at a State University.

An "after only" group (N = 9) was given the questionnaire only after the test drive in order to check for pretest effects in the main before-after measures. A comparison of the after scores in the before-after group to the after only group yielded no significant difference between the groups. This limited sample suggests that the experience of rating the Pinto before the test drive did not bias the after drive ratings.

The data for this paper were originally collected as part of a study of the effects of test driving three different distances on ratings of a Pinto. The three drive groups were combined for this paper as the present analysis was by subject, not by experimental group (length of the test drive) and ratings of the Pinto did not vary by experimental group. The data are useful in terms of an analysis of the hypotheses tested in this paper and fit the hypotheses well; however, it must be recognized that a limitation of the data was that it is a secondary analysis.

Conceptual and Operational Measurement

Predictive expectations (PRED_i) have been conceptually defined as the anticipated benefits from the product (Howard and Sheth 1969). The anticipated benefits were measured as the before ratings of the Pinto on 12 attributes (prestige, room of interior, engine power, number of options and accessories, attractiveness of interior styling, ride comfort, fun to drive, durability, well engineered, well made, handling, exterior styling). An example of an item appears below:

I EXPECT THE PINTO WILL:
 Roomy Small
 Interior : _ : _ : _ : _ : _ : _ : _ : Interior

Disconfirmation has been defined in two ways: perceived disconfirmation is the consumers post-usage perception of how well the product met his expectations, while the concept used in this study, inferred disconfirmation has been defined as the difference between after usage judgments of product performance compared to expectations (Oliver 1980, Trawick and Swan 1980). Disconfirmation of predictive expectations was measured as the difference between the after

minus before ratings of the Pinto on the 12 attributes noted above or n

$$\sum_{i=1}^n (A_i - \text{PRED}_i).$$

One potential problem with the disconfirmation measure is that the same scale was used twice which could lead to similar before and after ratings if the subjects attempted to be consistent. A factor that may have mitigated that problem is the time and driving experience between ratings which was about 15 minutes (short drive), 30 minutes (intermediate drive) or overnight usage of the Pinto (long drive). A second perspective on the disconfirmation measure is that Trawick and Swan (1980) have found that disconfirmation measured as in this paper and disconfirmation measured as the users perception of how well the product met expectations gave essentially the same results as correlates of satisfaction and were strongly intercorrelated.

In order to provide a measure of predictive expectations that was not a part of the disconfirmation measure, predictive expectation (EXP) was measured as the subjects anticipated overall satisfaction with the Pinto.

The LaTour and Peat (1979b) model incorporates a comparison level based on three components of which two were included in this study. One component is the anticipated attribute level, which the current authors believe is equivalent to predictive expectations, PRED_i . The second component is past experience, PAST_i , with attribute levels for similar products. This was measured by the subject's ratings of the automobile that he (she) had driven most frequently.

The adequacy of ratings of the car driven most frequently as an operational measure of PAST_i could be questioned especially if the car driven most frequently was quite different from a Pinto. About 40% of the subjects had compact or subcompact cars which would be similar to the Pinto. Another reason for using the most frequently driven car is that it should be a very salient experience.

In the LaTour and Peat model PRED_i and PAST_i are orthogonal. An examination of the data suggested that PRED_i and PAST_i were orthogonal, as the average simple correlation between the twelve attributes was $r = .08$ (without respect to sign).

The LaTour and Peat model includes attribute weights (W_1, W_2, W_3):

$$S = \sum_{i=1}^n (A_i - W_1 \text{PRED}_i - W_2 \text{PAST}_i - W_3 R_i) \quad (11)$$

The attribute weights are assumed to be equal in this paper. That assumption was made for two reasons. It seems reasonable given that past findings suggest "differential weights provide only limited benefits, compared to the use of equal weights." (Beckwith and Lehmann, 1973, pg. 141). Therefore for an exploratory examination of these models, this approximation should be adequate. In addition, a method for measurement of the weights has not been developed and to do so was beyond the scope of this paper.

The dependent variable, satisfaction has been defined in a number of ways, yet a common theme has been that satisfaction involves a post usage evaluation of a product or service (Day 1977). Satisfaction has been commonly measured using a simple rating of satisfaction and such methods have given results that agree with more complex measures (Miller 1977). Satisfaction was measured here after the Pinto was driven on a "very satisfactory" to "very unsatisfactory" 7 point semantic differential scale.

Analysis

The hypotheses predicted relationships between satisfaction and other variables. A simple correlation matrix was used to evaluate the hypotheses in a preliminary fashion and to see how the independent variables were related. Next, a set of multiple regression models were used to test the assumed predictors of satisfaction. The regression models were chosen such that no pair of predictors were correlated at a .5 level or higher. The .5 level is arbitrary but seems conservative (Green and Tull 1978, pg. 334). When the predictors were significantly intercorrelated the models were limited to an interpretation of only R^2 , not the Beta's. Intercorrelation can result in unstable Beta's, however the R^2 's are meaningful.

Results

The simple correlations in Table 1 suggest that satisfaction is most closely related to disconfirmation-past ($r = .60$) followed by initial expectation ($r = .51$), and disconfirmation of comparison level expectations ($r = .22$). A surprising finding was the lack of a significant disconfirmation of predictive expectations and satisfaction relationship. However, an examination of the data found a negative correlation between expectation and disconfirmation predictive expectations ($r = -.43$) and the positive expectation, satisfaction relationship ($r = .51$) suggests that expectation could be suppressing a disconfirmation-predictive and satisfaction relationship. Such may have been the case, as the regression analysis will show below, when expectation and disconfirmation predictive were included as predictors, both variables were important in determining satisfaction.

The first model (I) of Table 2 indicated that disconfirmation predictive was not a significant predictor of satisfaction unless included in a model, Model II, with expectation. Most of the influence on satisfaction was due to the expectation term, Beta = .70 for expectation versus .44 for disconfirmation predictive. Reasons for that finding were noted above. Disconfirmation of comparison level expectations alone (Model III), did not significantly [$P(F) = .1$] predict or explain much variation in satisfaction ($r^2 = .05$). Expectation and disconfirmation comparison exp. (Model IV) were able to explain a little less than a third ($r^2 = .31$) of the variation in satisfaction.

Model V with the disconfirmation of past performance expectations as a predictor indicated that disconfirmation-past alone explained about 36% of the variation in satisfaction. Adding expectation, Model VI, increases satisfaction explained ($R^2 = .42$). A Model (VII) with disconfirmation of both predictive and past performance expectations suggest that without expectation satisfaction is only related to disconfirmation-past. However, when expectation, disconfirmation of predictive and past are tested as predictors, all three are factors influencing satisfaction (Model VIII) and expectation is the most important predictor (Beta = .48). However a limitation of Model VIII is the high intercorrelation between expectation and the other predictors.

Discussion

The results gave very modest support of the LaTour and Peat model where satisfaction is directly related to the disconfirmation of a comparison level composed of subjectively perceived product performance from which predictive expectations and past performance on similar products are subtracted. The simple correlation ($r = .22$) between satisfaction and disconfirmation of a comparison level was significant but explained little variation in satisfaction. However, a part of the basic concept advanced by LaTour and Peat, that satisfaction is sensitive to perceived product

performance minus past performance on similar products was strongly supported. The results are congruent with findings of LaTour and Peat who created expectancies due to past experience with the product, information from the manufacturer and the experience of other users. They found a past experience effect but no effect of manufacturer or other users on satisfaction. LaTour and Peat's basic finding has been supported by a study that was quite different from theirs in the product, subjects and setting. A major conclusion is that models of consumer satisfaction need to incorporate the disconfirmation of past performance expectations.

In contrast to other research (Swan 1977, Oliver 1979, 1977) satisfaction was not related to the disconfirmation of predictive expectations unless that variable was included in a model with expectations. The negative relationship between expectations and the disconfirmation of predictive expectations shows that those with high expectations had low disconfirmation scores and vice versa. A potential problem with the operational measure of confirmation is that of a ceiling effect on the measurement scales. If an individual expected the Pinto to perform well on an attribute (before rating = 7) and it did so (after rating = 7) the disconfirmation score would be zero (disconfirmation = after-before). A low expectation allows more room on the after scale for improvement to yield a higher disconfirmation score. However, slight satisfaction could be expected from a customer who expected poor performance and received mediocre. Another potential measurement problem was the use of the same scale as the before and after measures.

It appears from this study and prior research (Oliver 1977, 1979; Swan 1977) that the initial level of expectation is a predictor of satisfaction in addition to a disconfirmation effect. This may be due to the ability of expectation to capture an effect of the level of performance that is independent of confirmation. The argument is similar to what was noted above. If an individual had past performance on an auto of 26 miles per gallon and another auto was expected to and did yield 28 miles per gallon, such a customer should be more satisfied than an auto owner who had past experience of 18 miles per gallon in contrast to another car that expected and gave 20 miles per gallon. The confirmation is equivalent, +2 miles per gallon but the level of performance is higher in the first case.

Work on expectations and consumer satisfaction is proceeding along at least three lines. Oliver has investigated components of and the process of consumer satisfaction. LaTour and Peat have suggested that expectations may involve different reference points, in particular this paper supports the hypothesis that the disconfirmation of past performance expectations is related to satisfaction. Finally, Swan and Trawick (1980) have found that satisfaction is related to the disconfirmation of two different kinds of expectations: (1) predictive expectations, which were not significant in explaining satisfaction in this paper and (2) desired expectations which represent the level of product performance that is necessary to please or satisfy the consumer. Work is needed to integrate and empirically test the different approaches to understanding consumer satisfaction.

An approach to the topic of disconfirmation that has received some attention in the literature is Assimilation/Contrast effects (Olson and Dover 1979). That approach is beyond the scope of this work. We feel that it was reasonable to omit assimilation/contrast for two reasons. First, assimilation/contrast would have their effects on the after measures of product performance and would be useful in terms of understanding why a particular objective level of product performance received a certain subjective rating. The subjective after ratings were measured and used in this study to define disconfirmation. This study was not designed to explain the after ratings rather they

were used as basic data. A second reason why assimilation/contrast was omitted is that the approach has criticized on a number of grounds which are too numerous to cover here, (Oliver 1977, Olson and Dover 1979).

Conclusions

In conclusion, this study found that the disconfirmation of expectations based on the past performance of similar product expectation were the strongest predictors of satisfaction. A surprising result was that the disconfirmation of predictive expectations (how the product was anticipated to perform) were not related to satisfaction. Except for the work of LaTour and Peat, the effect of different sources of expectations such as past experience or the experience of others has not been investigated. Sources of expectations could be an important topic for future research in consumer satisfaction.

COMPLAINERS AND NONCOMPLAINERS REVISITED:
ANOTHER LOOK AT THE DATA

Kjell Grønhaug, Norwegian School of Economics and Business Administration
Gerald Zaltman, University of Pittsburgh

Abstract

The point of departure for the present paper is previous attempts to profile complaining, dissatisfied consumers. By reviewing the previous literature, three "models" were identified: the "resource", the "learning" and the "personality" model respectively. An empirical test of the three models reveals only modest differences between complaining and noncomplaining consumers. Marketplace participation was found to be the most meaningful explanatory factor.

Introduction

Over the past few years, interest in and research on consumer satisfaction and dissatisfaction (CS/D) and complaining behavior have grown rapidly. Symptomatically, a recent review of 73 publications in the field noted that only 12 of them had appeared prior to 1972 (Hunt 1977).

Previous research efforts reveal the underlying, though implicit, assumption that dissatisfied complainers and noncomplainers, respectively, are different. The following quotation clearly indicates this belief: "... it was hoped that demographic characteristics of such consumers could be found that would distinguish consumers with problems who had not complained from those consumers who had complained" (Kraft 1977, p. 79). Much of the research emphasis has been directed toward profiling the complainers and noncomplainers by stable, sociodemographic characteristics such as age, education, and income. Such characteristics may definitely be useful as resource-related or social indicators (Bauer 1966), but there are definitely reasons why such indicators only exhibit modest descriptive and explanatory power in a consumer behavior context (cf. Sheth 1977).

Previous Research

At the more specific level, the following conclusions may be drawn from previous research:

- Only a fraction of the dissatisfied consumers actually takes overt action and complains. Andreasen and Best (1977) in a telephone survey conducted among 2,400 households found that the consumer (buyer) was dissatisfied in one of five purchases, but in less than 50 percent of these cases did he or she take any action. A recent review of the complaining behavior studies (cf. Robinsen 1978) strongly supports these findings. Although variations in propensity to complain are observed across studies, the overall conclusion to be drawn is that only a fraction of the dissatisfied purchasers are overt complainers.
- As noted above, various sociodemographics have been applied extensively in previous research to profile the complainers and noncomplainers, respectively. The results are, however, in no way conclusive. Liefeld, et al. (1975) found that Canadian consumers who had written complaint letters were middle-aged, better educated, earned higher incomes, and more represented by managerial and professional heads of households. Similar findings regarding the use of demanding sources of complaints have been reported by Grønhaug (1977), Zaichkowsky and Liefeld (1977), Kraft (1977) and

Warland et. al. (1975).

With regard to complaining in general (and, in particular, when looking away from complaining through the more demanding sources), the descriptive and predictive power of the various sociodemographics reveal very mixed results. By relating various sociodemographics (age, education, income, place of living, social status, occupation) to the propensity to complain due to a perceived dissatisfaction with a variety of nondurables (milk, meat, coffee, vegetables) and durables (textiles, cars), Grønhaug (1977) found the sociodemographics do possess no descriptive or explanatory power. Warland, et al. (1975) found, on the other hand, by relating the action due to the "most recent, salient negative experience in the marketplace" (p. 151), that the active complainers in general are younger and above average with respect to social status, income, education, and group membership. Zaltman et al. (1978) found age negatively related to propensity to complain. Granbois et al. (1977) found that sociodemographics overall possess almost no descriptive power. For some products, however, sex was found to possess some descriptive power. Wall, et al. (1977) found in a sample of female buyers of clothing that age was somewhat negatively related to the propensity to complain. Lawther (1978) found that consumers who are less socially integrated were less prone to make overt complaints than were the more integrated consumers.

The apparently inconsistent findings regarding the descriptive and explanatory power of the sociodemographics have led researchers to include other variables in their research. Inclusion of perceptual variables have revealed the almost self-evident finding that the more aware an individual is of defects, the higher the propensity to complain (cf. Kraft 1977, Zaltman et al. 1978). Also, attribution theory in terms of perceived causes to the dissatisfaction has been applied in the context of complaining behavior, revealing very promising and insightful results (Valle and Wallendorf 1977, Krishnan and Valle 1979). Personality characteristics have also been applied in attempt to profile complainers. Wall et al. (1977) found some items related to personality (liking/disliking, ways of perceiving things and self confidence), to possess some descriptive power among a sample of female buyers related to satisfaction/dissatisfaction with clothing. In an attempt to describe the personality profiles of consumer complaint letter writers, Zaichkowsky and Liefeld (1977) concluded however, "... that consumer complaint letters cannot be distinguished on the basis of personality types" (p. 128). In other words, the attempts to include various personality traits cannot be considered as successful.

The research on consumer satisfaction/dissatisfaction and complaint behavior is still in its infancy. Several objections regarding previous research may be made (cf. Ølander 1977, Haines 1979). No attempt will be made to discuss the inherent weaknesses in previous research. However, we would like to address the reader's attention to the lack of explicit arguments why and how the various indicators used should discriminate between complainers and noncomplainers, respectively.

Making the Assumptions Explicit

As noted above, in most of the previous research the assumptions underlying the choice of concepts and models have been more or less implicit. By reinterpreting previous research, the following assumptions (or models) can all be traced.

(1) The resource model: To make overt complaints requires resources. Resources are not equally distributed, and thus the propensity to complain will vary across the members of the society. This type of model (or argument) has determined very much of the consumer and welfare policy. Sociodemographics -- in particular, age, income and education -- have all been treated as individual resource indicators (cf. Atkinson 1975, Bauer 1966, Rein 1976).

(2) The learning model: Learning plays an important role in consumer behavior (cf. Howard 1977). Products and brands are learned; expectations and attitudes are learned; and how to handle purchases and complaints is learned. The basic underlying assumption or model in the CS/D-research is that "knowledge is power", i.e. the experienced, welltrained buyer will be better off. Learning in terms of awareness of unfair marketing practices and knowledge about consumer rights has been included in previous research (cf. Kraft 1977, Zaltman et al. 1978, Lawther 1978).

(3) The personality model: Some recent attempts have been made to incorporate personality variables into the research on CS/D (cf. Wall et al. 1977, Kraft 1977). The underlying assumption is that certain personality characteristics, such as high degree of self confidence, is associated with ability to perceive dissatisfaction and handle complaints.

In focusing on complaining behavior, we will -- as in previous research -- consider perceived dissatisfaction as a prerequisite to overt complaints. Based on the previous discussion, variables will be borrowed from the "resource", the "learning", as well as the "personality" model in order to describe and explain complaint behavior.

Methodology

Source of Data

Data used in this paper are from a large research study which investigated the consumer problems of the elderly. The data were obtained from two structured mail questionnaires which were developed from focus group interviews. The questionnaires were sent to 4,000 consumers between the ages of 25 and 80 who were members of a national panel maintained by Market Facts, Inc. Usable responses covering both waves (spaced by a six-month interval) were 2,849. The response rate to the original 4,000 questionnaires was 71 percent. The response rate for the second wave was 90 percent of the first wave sample.

The Sample

Due to the purpose of the data gathering, the elderly were deliberately oversampled. Compared to the U.S. population, the sample is skewed toward the elderly, which is due to deliberate disproportional sampling due to the focus of the study and the data gathering. Furthermore, the sample shows a slight underrepresentation of high school graduates and a moderate overrepresentation of college graduates. Compared to the U.S. population, the annual income in the sample was somewhat higher. In addition, it should also be noted that compared to the national population, the sample had a lower fraction of individuals whose spouses were no longer living, and fewer males living alone.

Measurement

Reported below are the measurements used in this study: Dissatisfaction. In order to map dissatisfaction, the following measurement was used. The respondents were confronted with a rather long list of products and services, and the following question was asked: "Please read the products and services listed below and 'X' all of those where you felt bad about your buying experience". From this operational definition, it follows that no restriction in time is given; in other words, many of the reported "bad buying experiences" may have taken place a long time ago. A summary measure for dissatisfaction across products was worked out by adding up the "bad buying experiences" (range: 0,, 21).

Complaint. If dissatisfied, the consumer (buyer) may react in several ways. This was mapped in the following way. For the "worst buying experience" a list of 12 different actions, which also included "no action", was given to the respondents, and the following question was asked: "Please 'X' below any actions you took because of the problems you had." The various actions listed may definitely put different requirements on the dissatisfied consumer. Actions requiring some sort of overt behavior directed toward the marketer or consumer agency were labeled "activist" complaint strategies.¹ In this paper the persons applying the "activist" strategy were contrasted with the "passivist", i.e., those who "took no action at all".²

Resources are often thought of in terms of money/economy. However, the individual resources should in no way be restricted to money/economy only. Here a distinction was made between the following types of resources: economy; problem solving capacity; health; time, and social resources. Several indicators were used to map the resource dimensions: economy (income, financial problems); problem solving capacity (education, decision-making skill, planning horizon); time available; health (age, various health problems); social resources (social contacts, perceived problems in getting help with consumer related problems).³

Learning was measured by mapping buying experience and knowledge, i.e. ability to handle the buying problems.

Personality. Indicators mapping involvement, self-confidence, and perceptions of being treated fairly besides perceived consumer influence were applied in order to map personality.

The measurements applied include self-reports on perceptions and behavior as well as sociodemographics. The dissatisfaction and complaint measures coincide to a substantial degree with measures used in previous research. With regard to the resource measures, the sociodemographics

¹The "activist" strategy included "complained to the person who sold me the product or service", "complained to the company or store", "complained to a consumer agency", "complained to a public agency or my congressman", "complained to a newspaper or magazine", and "consulted or hired a lawyer to protect my interests".

²Besides the "activist" strategy, strategies related to "word-of mouth", "stop buying", and "the passivist" strategy ("no action") were located. By examining the various strategies according to the variables (indicators), the "activist" and "passivist" strategies were really found to represent the extremes.

³The indicators included the mapping of several "life events" such as the experience of financial crises and health problems.

(income, education, and health) have been extensively applied in previous research (cf. Sheth 1977). The "life events" (cf. "financial crisis" and "health problems") have not been applied in previous research, and are included in order to indicate changes. The various indicators related to knowledge, experience, planning horizon, and perceived decision-making skill, have all been widely used in previous consumer research.

Findings

Reported below are the major results from this investigation: 30.3 percent of the respondents had not any "bad buying experience". Of those who had at least one such experience, 834 respondents had applied the "activist" strategy, and 432 the "passivist" strategy. These two subsets, the "activists" and the "passivists", will constitute the sample of analysis (n = 1,266).

Table 1 summarizes the results from the bivariate analysis breaking down the various variables by the two strategies applied. The statistical procedure is t-test applied to differences of means; i.e. the differences between the "passivist" and "activist"-scores. The results are surprising in term of lack of associations between complaint strategy and the various indicators. Closer inspection of Table 1 reveals that the active complainers are:

- higher in experience (i.e., buying experience);
- higher in income;
- higher in education; and
- they tend to be younger than do the noncomplainers.

However, as seen from Table 1, none of the indicators related to health (except age), time, social resources or personality revealed any differences between the complainers and noncomplainers.

Table 1

Variables Related to Resources, Learning, and Personality by Complainers and Noncomplainers

	Complaint Strategy		Total	Significance Level
	"Passivist"	"Activist"		
1. Resources				
(a) Economy:				
Income	4.3225	5.1248	4.8513	p < .001
Financial problem	.1019	.0899	.0940	n.s.
(b) Problem-Solving Capacity:				
Education	3.2689	3.2422	3.3704	(p = .0625)
Decision-making skill	1.7870	1.8861	1.8530	n.s.
Planning horizon	2.3889	2.9140	2.3276	n.s.
(c) Time: (perceived time)				
	2.5995	2.6559	2.6367	n.s.
(d) Health:				
Age	5.4014	5.2197	5.2817	(p = .0477)
Health problems:				
Vision	.4828	.4746	.4774	n.s.
Movement	.1435	.1415	.1422	n.s.
Depression	.0116	.0072	.0087	n.s.
Physical activity	2.4375	2.4868	2.4700	n.s.
(e) Social Resources				
Social Contacts	6.9630	7.1823	7.1074	n.s.
Help	2.7487	2.7846	2.7725	n.s.
2. Learning				
Experience	2.6019	3.1451	2.9597	p < .001
Knowledge	2.7176	2.7806	2.7591	n.s.
3. Personality				
Involvement	2.1505	2.1427	2.1453	n.s.
Self-confidence	1.9352	1.9017	1.9131	n.s.
Fair Treatment	2.1276	2.1609	2.1496	n.s.
Consumer Influence	1.8156	1.8107	1.8123	n.s.

Discussion

Several questions might be raised based on the preceding data presentation, such as: Why are there so few differences between the complainers and noncomplainers, and more basically, what do the results really mean? We will address our attention to the last question.

The indicators for which there are discrepancies are not necessarily unrelated. By inspecting the intercorrelation matrix, the following picture emerges:

Table 2

Correlation Matrix: "Activist", Education, Income, Age and Experience*)

	Experience	Education	Income	Age
"Activist" ^x	.1453	.0650	.1144	-.1119
Experience	x	.1467	.1964	-.2304
Education		x	.3483	-.1351
Income			x	-.3544

*) all the correlation coefficients are significant at the .001 level.

Here ordinary product-moment correlations have been applied. In doing so the nominal scaled complainer categories are turned into dummy variables (i.e. "activist" = 1, "passivist" = 0). Experience is here the summary measure of previous buying experiences. Age and education are in fact ordinal scaled variables. However, only modest differences were detected by applying nonparametric measures of association.

The correlation matrix reveals that "activists" are positively related to experience, education, and income, but negatively related to age, just as demonstrated in Table 1. However, it is also evident that the various descriptive variables are intercorrelated. By calculating the various partial correlations and controlling for the subsequent variables, the following emerges:

$r_{act., exp.}$ (controlled for education, income, age = .1130 (p < .001)).

$r_{act., age}$ (controlled for education, income, experience) = .0560 (p = .048).

$r_{act., educ.}$ (controlled for age, income, experience) = .0166 (p = .558).

$r_{act., inc.}$ (controlled for education, age, experience) = .0678 (p = .017).

In other words, the "experience" variable by far possesses the greatest descriptive power. Similar results were found by performing multiple discriminant analysis. However, the predictive power of the derived discriminant function was found to be modest as assessed by comparing the number of cases correctly classified with the by chance result, which also follows from the rather low correlation coefficients as demonstrated in Table 2, and the lack of association between complainers (or noncomplainers) and most of the predictors as shown in Table 1.

When taking a closer look at the applied "experience" measure, it obviously relates to buying activities. Or, maybe better, the measure represents a rough proxy for market-place participation. And, according to the present authors, this represents the key to the explanation. First, buying is not the sole activity with which man is preoccupied, nor does this activity have to be the most important one.

In fact, the individual member of the society is confronted with various types of constraints including limited time and span of attention.⁴ This, in turn, directs our attention to one of the almost forgotten elements in a marketing context, namely, that the consumer role may be one of the many roles played by the individual. He or she will furthermore put more or less emphasis on this role. The relative importance of this role for him or her will be closely related to the time devoted and the activities performed in the context of this role. And this role will be played across all social strata!

Why is this role (marketplace participation) related to, or better, associated with income, education, and age (cf. Table 2)? First, economic resources are a prerequisite to participate in the marketplace as a buyer. Second, income and education are positively correlated, and thus by controlling for income, the association between marketplace participation and education drops dramatically. One intriguing explanation may be proposed for the negative relationship between age and complaining, which is that this phenomenon is caused by a cohort⁵ effect. However, by controlling for marketplace participation, the effect of age on noncomplaining is (as demonstrated above) dramatically reduced.

The marketplace participation argument launched above may also shed some light on previous findings. The results reported by Warland et al. (1975) may partly be explained by variation in marketplace participation. The impact of the sociodemographics (which is in the same direction as the findings presented here) may also to some extent be explained in terms of variations in marketplace participation. Similarly, the impact of sex in findings reported by Wall et al. (1977) and Granbois et al. (1977) may be explained in terms of products primarily dealt with by women, and represent thus an artifact introduced by the products studied (cf. Rosenthal and Rosnow 1969). Symptomatically no differences were detected between sexes when applying our aggregate "marketplace participation" measure. But why are our deflections for the "marketplace participation" measure not more pronounced? The explanation is probably due to the very rough nature of this proxy measure. Refined measurements taking such factors as allocation of time, the variety of activities performed, and importance placed on such activities would probably yield much stronger results.

The findings reported and explanations provided do also have consumer policy implications. First, the elderly, the poor and the individual low in education do not necessarily react more passively to perceived dissatisfaction -- as demonstrated above -- than do the individuals higher in resources, which clearly seems to contradict public policy practice. In fact, for groceries the low income consumers were found in several studies to be higher in price knowledge than were the high income consumers (cf. Goldman 1977, Gabor and Granger 1961), which is in concordance with the fact that the lower income consumers necessarily have to be more conscious due to less economic resources. This "apparent" lack of the "expected" negative relationship between being active in complaining and low in income and education and high in age may also be due to the following explanation. The

more involved in the marketplace, the higher the probability of being exposed to buying problems ($r = .224$; $p < .001$). In addition, the following argument related to social class and consumption style seems to be relevant: Income and education are both well-known indicators of social class. Furthermore, basic values and consumption patterns vary across the various social strata. Expressive values and thus emphasis on expressive consumption is more frequent among the lower classes as compared to the predominance of instrumental values and behavior in the upper social classes (cf. Segal and Felson 1972). Intuitively, expressive consumption is less demanding, the consequences may be easier to foresee, and the purchases are thus less likely to produce dissatisfaction. Thus the "expected" higher fraction of dissatisfied, passive consumers is not showing up in the research. On the other hand, if the consumption aspiration level of the lower social segments is raised, this may lead to higher degree of perceived dissatisfaction.

EFFECT OF SATISFACTION AND ITS ANTECEDENTS
ON CONSUMER PREFERENCE AND INTENTION

Richard L. Oliver, Washington University
Gerald Linda, Marsteller, Inc.

Abstract

Theorists and researchers in the satisfaction area now generally agree that product satisfaction intervenes between expectancy disconfirmation and various postpurchase cognitive states including attitude and behavioral intention. Research in a variety of settings has supported the effect of expectation and its disconfirmation on satisfaction, but only a small number of studies addresses the cognitive consequences of satisfaction decisions and none reports data on choice processes such as brand selection. This study examines the influence of satisfaction and its determinants on behavioral intention and product preference in a simulated two-stage consumer usage situation. Generally it was found in both overall and summed attribute analyses that satisfaction was a function of expectation and disconfirmation, that intention was a function of satisfaction, and that preference was influenced by satisfaction and disconfirmation, the latter having the greater effect.

Introduction

The field of consumer satisfaction, long neglected by cognitive consumer behaviorists, is now beginning to develop a research tradition. Based on theoretical works by Engel, Kollat, and Blackwell (1968), Howard and Sheth (1969), Andreasen (1977), and Day (1977), research in both the laboratory and the field is proliferating. This has prompted reviewers (Day 1977, Olander 1977, Oliver 1977, LaTour and Peat 1979) to call for theoretical extensions and methodological refinements. Specifically, researchers have been asked to position satisfaction and its related constructs in cognitive models of consumer choice and to experiment with more coherent measures of the expectancy disconfirmation process.

Theoretical Perspective

A number of theories have been proposed to explain satisfaction decisions. These have been reviewed in detail elsewhere (Anderson 1973, Oliver 1977, LaTour and Peat 1979) and are not repeated here. In summing up the evidence to date, Oliver (1980b) has suggested that the most epistemologically efficient explanation derives from Helson's (1948, 1964) adaptation level theory which suggests that judgments of newly perceived stimuli are affected by prior experience with the general class of objects (the adaptation level) and the discrepancy perceived between the new stimulus and previously determined stimulus levels. Discrepancy, Helson noted, was a relative individually-specified phenomenon and has no necessary correspondence to objective differences.

Helson's (1964) theory may be viewed as isomorphic with the process of expectancy disconfirmation thought to occur in satisfaction judgments, differing only in terminology. One's expectation level, however determined, performs the function of an adaptation level. States of satisfaction/dissatisfaction are hypothesized to result, in part, from a comparison between one's perception of product performance and the expectation level. This discrepancy is known as (positive or negative) disconfirmation. Because the expectation level provides a baseline about which disconfirmation takes place, satisfaction is easily shown to be an additive function of expectation and disconfirmation. This interpretation was first suggested and empirically demon-

strated in the industrial and social psychological literature (Ilgen 1971, Weaver and Brickman 1974) and has received limited support in consumer environments (Oliver 1977, Swan 1977, Madden, Little, and Dolich 1979). None of these studies extended the analysis to actual post-exposure choice behavior, however.

Measurement Issues

Researchers remain in disagreement over the most appropriate way to measure the antecedents of satisfaction and satisfaction itself. The concept of expectations, in particular, has been somewhat evasive from a psychological standpoint. Perhaps the most general workable definition is that of Katona (1964) who referred to expectations as a "subclass of attitudes that point to the future (p. 34)." As such, they may be seen as predictions of affect.

Early satisfaction researchers pursued a cognitive approach to the measurement of expectation and used product and attribute ratings as proxy variables for one's expected performance. Later, Olson and Dover (1979) and Oliver (1980a) adapted Fishbein (1967) scaling to this same task. Olson and Dover used only the belief elements of Fishbein's *ab* scales while Oliver combined the cognitive and affective dimensions to provide an evaluative belief score. Both approaches demonstrated the intended effect, but neither was a pure measure of predictive affect.

Disconfirmation has followed a similar developmental process. The discrepancy concept was initially viewed in the objective sense. Experimenters using manipulations in the laboratory assumed that disconfirmation existed whenever subjects' product experience deviated from the materials used in the expectation-creation task. Unfortunately, manipulation checks on perceived discrepancy were not taken. As a result, neither disconfirmation nor its magnitude and direction were determinable. Later researchers used the difference scores between preexposure and post-exposure attribute ratings (Oliver 1977, Swan 1977, Madden, Little, and Dolich 1979). While this approach to discrepancy was "real" in the sense that it involved a mathematical comparison between perceived performance and some prior cognition, it proved to be confounded with expectation and, on a conceptual plane, ignored the "surprise" value of disconfirmation. To address these problems, "better than expected -- worse than expected" scales have been used by Oliver (1977, 1980a) and have shown promise as predictors of satisfaction and other postexposure cognitions. This approach will be expanded here.

Finally, satisfaction has been measured using a variety of postexposure variables having affect as a common theme. Most researchers would agree, however, that product evaluations and attitudes are not operational definitions for satisfaction. Other approaches include Likert scales and "raw" satisfied-dissatisfied items. The latter have the greatest face validity but tend to produce positively skewed distributions reflecting a halo effect (Andrews and Withey 1976, Day and Bodur 1977). In comparison, multi-item Likert or semantic differential scales present the problem of finding a sufficient number of synonyms for satisfaction without also sampling the affective like-dislike domain. Interested readers are referred to some preliminary findings reported by Westbrook and Oliver (1981).

Study Perspective and Objectives

In an effort to extend further the basic satisfaction model to consumer intention and choice, a two-stage field study of consumer reactions to the preprocessing of new apparel fabrics was performed. In accord with the theoretical perspective of expectations as predictions of affect, expectations were viewed as a priori perceptions of the amount of satisfaction to be received from the product as a whole and in terms of its salient attributes. This required that measures of expectation be obtained before the exposure situation was encountered.

To maintain a consistent perspective to the expectancy disconfirmation process, disconfirmation was viewed as the perceived satisfaction deficit (surplus) after the product experience. Measured in terms of less (more) satisfied than expected, disconfirmation as viewed here focused on the comparative process and not on actual states of performance per se. The "mathematics" of discrepancy judgments were made by the subjects who responded with net feelings of fulfillment or lack thereof. As before, both overall and attribute-specific disconfirmations were elicited.

The last part of the second study phase, in keeping with the temporal nature of the model, required that satisfaction and subsequent cognitions be obtained. Care was taken to insure that the proper sequence of variable measurement was maintained to overcome partly problems associated with the necessity for concurrent measurement in this last study phase.

The approach taken here differs in a number of respects from prior studies and may provide a different perspective to satisfaction processes. First, the measurement of satisfaction and its antecedents involved consistent referents across study stages. Specifically, operationalizations of expectations of satisfaction, disconfirmation of satisfaction, and satisfaction itself were constructed with the same semantic phrases and attribute lists. Previous studies have confounded a host of different referents and algebraic difference scores in testing the basic model. While a multiple indicator approach will eventually be required for purposes of construct validation, research on satisfaction could benefit greatly from attempts to establish a coherent framework of satisfaction-related semantic concepts.

Secondly, attribute-specific satisfaction processes were compared to an overall approach in an effort to determine if the scheme suggested here operates in both modes. Attribute-specific measurement may not fully represent all salient attributes for all subjects, but does provide diagnostic information on an individual attribute basis. In contrast, overall scales serve to capture the totality of the cognitive process at the sacrifice of detail and, in addition, can be evaluated on the basis of internal consistency reliability. To date, few studies have been conducted using attribute-specific and/or multi-item overall scales for satisfaction and expectancy disconfirmation and none has compared these two variations. Hopefully, some insight into the relationship between specific and general satisfaction processes will be evident from this analysis.

Method

Overview

A mall intercept study of male and female shoppers was conducted in a suburban Chicago shopping center. After an initial screening to determine eligibility requirements for the product group under investigation, subjects were asked to examine two pairs of men's sleeping apparel having different texture and softness. All product samples were recently manufactured and contained the sizing and other fabric conditioners used to facilitate construction

of the garment. In the first stage of the study, the subjects indicated how satisfied they expected to be with both garments and garment attributes in daily normal usage and care, their interest in buying the products, and their preference for one over the other.

In the second stage of the study, the subjects were shown the identical pair of sleeping apparel after each had been laundered five times. Laundering removes the sizing and other pretreatment chemicals and generally makes fabrics softer, although to varying degrees. Subjects now responded to overall and attribute-specific disconfirmation scales on each product, then to overall and attribute-specific satisfaction scales, and finally to purchase intention and new preference.

Subjects

Based on the sponsoring company's directive, 500 mall shoppers were approached on a quota basis to achieve a final sample of 250 males and 250 females. Males were required to be fifteen years of age or older (the target group) and to wear pajamas at least twice a week. Females, known to be the primary purchasers of men's pajamas for members of their families, were required to be 21 or older, to have males 15 years or older who wear pajamas at least twice a week in the household, and to usually buy the pajamas for the men in their family. The average age of males in the final sample was 38 years and that of females was 46.

Measures

Attribute-specific variables. Evaluative criteria for the attribute-specific measures were obtained by pretesting a list of 20 factors known to be related to judgments of wearing apparel on an independent sample of 400 consumers. Based on mean importance scores, a shorter list of nine attributes was judged sufficient by company management and is not reported here for proprietary reasons. Based on the Katona (1964) approach, expectations were measured by asking the respondent to indicate how satisfied "you or the male you would buy for" would be with regard to each attribute. Scales ranged from "very satisfied" to "very dissatisfied." The nine expectation scores were then summed to form the attribute expectation measure. Pre-exposure preference, in turn, was based on the subjects' actual preferred choice of one pair of sleeping apparel over that of the other.

Postexposure attribute disconfirmation was measured on 15-point scales where the midpoint defined each attribute as expected. The negative disconfirmation pole described attributes as worse (e.g., not as soft) than expected while the positive pole described them as better (e.g., softer) than expected. Attribute satisfaction was obtained after all disconfirmation measures were taken to insure that the measurement process maintained the temporal ordering of the underlying framework. The same items used for one's expectations of satisfaction were used here as well except that the lead-in to the satisfaction items simply asked the respondent to indicate how satisfied he/she was now. Finally, postexposure intention was measured on a five point "definitely would buy" to "definitely would not buy" scale while postexposure preference was obtained by asking the subjects to reconsider the pajamas a second time and to choose the pair they now preferred. The criterion used in the study was change (no change) in preference coded in 0-1 format.

Overall variables. A consistent three-referent scheme was used to measure overall expectation, disconfirmation, and satisfaction. Based on extensive work by Andrews and Withey (1976) and Campbell, Converse, and Rodgers (1976) on the meaning of satisfaction, two constructs having close (but not identical) semantic properties were combined with satisfaction (expressed as satisfied-dissatisfied) to form three-item scales. The two related constructs, happiness

(happy-unhappy) and pleasantness (pleasant-unpleasant) were thought to reflect emotions close to those involved in a satisfaction response. Thus, expectation was measured by asking respondents how (satisfied, happy, pleased) they expected to be; disconfirmation was obtained on a "more than-less than" (satisfied, happy, pleased) scale; while satisfaction was an outright rating on the three items. Alpha reliability coefficients over the total sample were .85, .79, and .94 for expectation, disconfirmation, and satisfaction respectively.

Analysis

Because the males in the sample were judging their own satisfaction while females were judging satisfaction vicariously for the male they would buy for, all analyses were run separately for men and women. In addition, separate analyses were performed for the overall and summed attribute scales to determine if equivalent results would be found. Finally, only the initial preferred pair of pajamas was analyzed across the two stages of the study. Results for the second (initially least preferred) pair were virtually identical to the first and are not reported here.

The models tested derive from those suggested in Oliver (1980a). His basic hypotheses were adapted to the context of the present study and appear as follows:

$$\text{Satisfaction} = f(\text{Expectation, Disconfirmation})$$

$$\text{Preference} = f(\text{Expectation, Disconfirmation, Satisfaction})$$

$$\text{Intention} = f(\text{Expectation, Disconfirmation, Satisfaction, Preference})$$

Elementary path analysis was employed to test these propositions. Of interest are the magnitudes of the coefficients of determination and the comparative magnitudes of the (standardized) regression coefficients attributable to each of the independent variables within equations for each sample taken separately and for each variable across samples. Relative stability of the weights across situations would lend further support to the basic expectancy disconfirmation model.

Results

Zero-order correlations between all variables across the two sample and measurement groups are shown in Table 1. The data are remarkably consistent across all analyses. Satisfaction was significantly correlated with its hypothesized antecedents in all cases, although disconfirmation yielded the highest correlations in the female sample. Preference (coded as change in preference) was most highly correlated with disconfirmation in all cases although significant correlations were also obtained with satisfaction and to a lesser degree, with intention. Surprisingly, preference was not correlated with expectation, a result explained more fully in the discussion section.

Finally, intention was universally correlated with all antecedents. In fact, with the exception of the preference variable, the magnitudes of the intention intercorrelations reflect the temporal nature of the proposed scheme exactly ($r_{53} > r_{52} > r_{51}$). Although no sex differences were found in this analysis, the overall scales produced higher associations, particularly for the intention-satisfaction relationship.

Table 2 shows the results obtained when the suggested models were tested in a sequential path analysis. The data show, first, that satisfaction was an additive combination of expectation and disconfirmation, reflecting the low degree of multicollinearity between these measures (Table 1). Moreover, disconfirmation appeared to be the stronger of the

two effects, particularly for women respondents. Between 35% and 50% of the variance in satisfaction was explained by this two-variable scheme.

The results for preference change were dominated mostly by disconfirmation and, to a lesser degree, by satisfaction. All analyses yielded roughly equivalent findings, explaining between 12% and 21% of the criterion variance. These figures compare to a theoretical maximum value of .52 for a dichotomous criterion having the probability of occurrence (.26) found in this study (Nunnally 1978). Female respondents appeared to place greater emphasis on satisfaction which accounts for the higher coefficients of determination for the female analyses.

Finally, intention was almost exclusively a function of satisfaction. The path coefficients were very high for the satisfaction variable and virtually zero for all other predictors including preference. All coefficients of determination were above .5 and it appears that the overall scales yield a more complete explanation than do the summed attribute measures.

Discussion

This study has addressed a number of issues which merit further elaboration. These include the structure of the theoretical framework, level of variable measurement, sex differences in response, criterion predictability (validity), limitations of the methodology, and further research directions.

Theoretical framework. The basic theoretical premise,

TABLE 2
STANDARDIZED COEFFICIENTS OBTAINED WHEN
SATISFACTION, PREFERENCE, AND INTENTION
WERE REGRESSED ON THEIR ANTECEDENTS

Criterion: Sample/Scale	Independent Variable				R ²

Satisfaction = f(Expectation, Disconfirmation) patterned after Helson's (1964) adaptation level theory, received consistent support. It appears that expectations do provide a standard against which product deviations are perceived. This finding adds further support to a growing number of studies which suggest this perspective (Oliver 1977, Swan 1977, Gilly 1979, Linda and Oliver 1979, Madden, Little and Dolich 1979, Oliver 1980a, Swan and Trawick 1980, Westbrook 1980). It should be noted that most all of these investigations were conducted in different contexts using two-stage measurement and a varied mix of products and services including automobiles, breakfast bars, flu inoculations, newly opened department stores, and fabric cleaners.

It is also of interest to note that all studies including the one described here have found that disconfirmation is the more potent of the two effects. In terms of the magnitude of the standardized regression coefficients, a ratio of one and one-half to one is not uncommon. While methodological issues provide a partial explanation in that disconfirmation and satisfaction are typically measured in close proximity after product exposure, this sequence of events conforms to the nature of the hypothesized cognitive response. Additionally, great care was taken in the present study to segregate the two measures through questionnaire sequencing, although it is admitted that separate instruments and longer time intervals between measurement will be required before this issue is resolved.

Summed attribute vs. overall measurement. Inspection of Table 2 shows that the overall bipolar adjective scales yielded marginally superior results to those obtained using summed attribute scales. The differences were most dramatic when coefficients of determination for the two scaling procedures were compared, particularly for the intention criterion. Sizable differences were also evident between the attribute and overall satisfaction path coefficients in the intention regressions.

Two explanations pertain. The first relates to current theoretical perspectives of cognition formation. If one adopts the approach taken by Fishbein and Ajzen (1975), the essence of constructs having formative elements is best

captured in summary statements (e.g., one's overall subjective norm). This appears to be true because any list of elements will in all probability be deficient for some subjects and extraneous for others. Secondly, summed attribute lists of diverse elements cannot be expected to have high internal consistency reliability. In contrast, the bipolar adjectives selected for the overall scales demonstrated adequate to high reliability for the three constructs tested here and are probably to be preferred unless diagnostic information is desired.

Sex differences. The data suggest that women responded with slightly greater magnitudes of effect in two cases. First, they placed greater emphasis on disconfirmation in the prediction of satisfaction and also on satisfaction in the prediction of preference. While the study was not designed to provide explanations for this observation, it may be that women were more involved in the decision. Involvement has been suggested as a moderator in reactions to product satisfaction situations (Olson and Dover 1979). Because the majority of men's sleepwear purchases are made by women, it is likely that their potentially greater involvement made them more sensitive to feelings of disconfirmation and satisfaction. The notion that disconfirmation perceptions are affected by product involvement has potential implications for practice and should be pursued in future research efforts.

Validity. The model as proposed quite adequately predicted intention to buy. In fact, coefficients of determination for cognitive criteria in excess of .5 are fairly common among the studies cited previously. The model can also be shown to predict (in a concurrent sense) postexposure attitude and other reactions including product ratings. Unfortunately, behavioral choice (here preference) was not predicted to the same degree, even taking into account the fact that the theoretical maximum R² value in this study was roughly .5. This is further clouded by the fact that disconfirmation and not satisfaction played a major role in one's postexposure preference. Typically, preference, like attitude, would be a significant function of satisfaction.

Further reflection suggests that the result obtained is that which would have been anticipated. Our criterion here is change in preference, not preference per se. Helson's (1964) theory suggests that expectations define the baseline for disconfirmation but that movement from level (change) is a function of disconfirmation only. Thus, postexposure attitude should be a function of expectation and satisfaction but attitude change (the difference) would be predicted best by the performance-expectation discrepancy. In fact, reanalysis of data from prior studies available to the authors suggests that this is indeed the case. This logic provides a reasonable explanation for the strong influence of disconfirmation on preference. The coefficients for satisfaction were significant, however, in three of four analyses, as hypothesized.

Limitations and future research directions. A number of limitations which detract from the contribution value of the study requires elaboration. Each, in turn, suggests an area of improvement for future investigations. First, the study did not involve an actual purchase situation with normal usage. Rather, these two necessities were "short-circuited" in the procedure. Although the product response was accurately duplicated, the lack of a myriad of extraneous factors normally present in real usage situations may have provided an overly sterile environment for respondents, contributing to an overstatement of the theory's validity.

Closely related to the preceding comment is the issue of the timing of the measures relative to their occurrence in a natural environment. Ideally, the study should have been replicated after each washing rather than after five consecutive washings. Thus, expectations would have been measured before the first wash and disconfirmation, satis-

faction, and revised expectations after the laundering. The revised expectations then become input to the cognitive response following the second washing. No study has looked at the process of satisfaction as a function of successive usage over time and work in this area is needed urgently.

A third issue surrounds the measurement of satisfaction and its antecedents. While each new study provides more focused perspective to different measurement vehicles, little consensus exists to suggest a one best approach. The three item bipolar adjective format used here demonstrated promise on two counts. First, the internal consistency appeared acceptable especially for measurement of satisfaction per se. And second, it is easily adaptable to expectation and disconfirmation items. Readers may object to the use of pleasantness and happiness as synonyms for satisfaction. The authors share similar reservations and welcome suggestions from other researchers.

Finally, the sample frame used here remains a potential source of error. A national probability sample was not used and one wonders how the results would have been affected. While the findings do not generalize beyond the mall sampling procedure used here, we have hopefully identified a close approximation to the process of satisfaction decisions used by consumers generally.

DEVELOPING BETTER MEASURES OF CONSUMER SATISFACTION: SOME PRELIMINARY RESULTS

Robert A. Westbrook, University of Arizona
Richard L. Oliver, Washington University

Abstract

Increased empirical study of consumer satisfaction has not yet been accompanied by commensurate refinements in the conceptualization and measurement of the construct. A review of the related literatures in job, health (patient), marital, and life satisfaction reveals that varying degrees of methodological rigor have been used to develop satisfaction measures, resulting in instruments as long as 80 items, but that little consensus on conceptual or measurement issues is evident. In an attempt to further satisfaction measurement in the consumer domain, a number of suggested multi-disciplinary approaches were combined in a two-product satisfaction instrument to test for response characteristics, reliability, and convergent and discriminant validity. Results in two separate pilot samples indicate that the highest reliabilities were achieved with semantic differential and Likert scales. These measures along with other verbal and graphic rating scales also demonstrated a high level of convergence and acceptable levels of discriminability.

Introduction

While interest in consumer satisfaction has grown rapidly in recent years (Hunt 1977, Day 1977, Day and Hunt 1979), there is little agreement on measurement of the construct. Empirical studies reflect a variety of different measures, although typically neither the reliability nor validity of these measures has been demonstrated. Not only does this hinder the interpretation and synthesis of research findings, but it also raises the possibility that applied studies in industry and government may be obtaining inaccurate assessments of prevailing satisfaction levels. Further attention to the development and evaluation of consumer satisfaction measures is clearly warranted. Accordingly, this paper reviews alternative satisfaction measures and presents preliminary findings of a measure validation study.

Conceptualization of Satisfaction

Prior to consideration of alternative measures, attention must be given to the conceptualization of consumer satisfaction and its relation to other theoretical constructs. While satisfaction is most readily associated with the purchase and consumption of specific products or services, it may also be relevant for shopping and patronage at retail outlets, for media usage, and even overall participation in the marketplace (Czepiel, et al. 1975). Thus, consumer satisfaction refers to an evaluative response concerning the perceived outcomes of experiences in the consumer domain, comprising acquisition, consumption, and disposition activity. These outcomes are often assumed to be evaluated according to the extent to which they fulfill consumers' expectations (Howard and Sheth 1969). However, other kinds of evaluative standards are conceivable, such as correspondence of perceived outcomes to those ideally desired or to the minimum outcomes considered acceptable. The more favorable the evaluation of perceived outcomes, the greater the satisfaction.

Central to the construct of satisfaction is the presence of affect. In connection with their evaluations of outcomes, consumers may experience varying degrees of feeling

or emotion. Favorably evaluated outcomes are associated with happy, pleasant feelings, and unfavorably evaluated outcomes with unhappiness, irritation, or regret. In addition, the notion of satisfaction implies some degree of conation in that the consumer is more or less inclined to repeat the behavior in question given recurrence of the situation in which it was initially performed.

With respect to theoretical conceptions of brand purchase behavior (Howard and Sheth 1969), satisfaction with a particular product occurs after purchase commitment but prior to any revision in evoked set, brand attitude, and brand (re)purchase intentions. A high level of satisfaction is believed to increase the likelihood that the brand in question will be included in the user's evoked set, increase the favorability of brand attitude, and increase the degree of intention to (re)purchase that brand (Oliver 1980). Low levels of satisfaction, or dissatisfaction, presumably have opposite effects and tend to motivate the consumer to seek redress or remedy by complaining to the seller or third parties.

Measurement of Consumer Satisfaction

Most research on consumer satisfaction has been concerned with specific products and services (Day and Ash 1979, Swan and Combs 1976, Andreassen and Best 1977, Oliver 1980) or retail outlets (Miller 1976). Satisfaction with other facets of consumer experience have been studied only infrequently (see Lundstrom and Lamont 1976, Westbrook and Newman 1978). Typically, measurements of satisfaction with products/services and retailers are based on direct subjective estimation by consumers of the intensity or frequency of overall satisfaction experienced. Most often, simple, single-item rating scales are employed. There has been little uniformity in the number of scale steps used or nature of verbal anchoring, however; they range from 3-point fully-labelled rating scales to 10- and 11-point variants labelled only at the extremes and midpoint. Comprehensive measure comparisons have seldom been undertaken, and investigators rarely report the reliability, much less the validity, of their measures.

Multi-item rating scale measures of product/service/retailer satisfaction have found application infrequently, despite their potential to reduce measurement error. In one of the few instances, Oliver (1980) used a set of six Likert-format items dealing with overall satisfaction, for which a high level of internal consistency was observed ($\alpha = .82$). Multi-item measures based on satisfaction ratings for individual product/service/retailer attributes have been conspicuously avoided (for an exception, see Morris 1977), most likely because of uncertainty as to the functional form in which the latter should be combined into overall satisfaction judgments.

In view of the complexity of the construct of consumer satisfaction, the predominant approach to measurement reflected in the literature may be naive. It is doubtful that the cognitive-evaluative, affective, and conative elements of satisfaction can be adequately captured in a single 5- or 7-point "very satisfied -- very dissatisfied" rating scale. If anything, such simplistic measures may be biased because of too few scale increments and the absence of explicit evaluative and affective anchoring along the scale continuum. Andreassen (1977) reports some evidence that a 4-point rating scale overreported satisfaction compared to judgments based on various open-ended

questions. Moreover, satisfaction studies have typically resulted in "bunching" of respondents at the upper end of the satisfaction continuum.

More comprehensive measures of consumer satisfaction are clearly needed. In searching for such measures, it is instructive to examine methods of measurement employed in studies of satisfaction with other domains beyond consumption. Accordingly, the following section presents a brief review of the major measures of job satisfaction, life satisfaction, marital satisfaction, and patient satisfaction.

Measurement of Satisfaction in Other Domains

Job Satisfaction

Of other disciplines which have studied satisfaction, none has a longer tradition than management/industrial relations. Job satisfaction has been studied intensively for some fifty years, and a substantial literature has accumulated (for a recent review, see Locke 1974). The predominant measurement strategy involves direct verbal self-reports on rating scales of various forms. Often these are simply single- or dual-item overall satisfaction ratings, but a number of complex instruments examining the various facets of satisfaction have also emerged. In a review of the simpler measures, Robinson et al. (1969) find most promising two rating scales, neither of which involves an estimation of satisfaction per se. One is the self-anchoring Ladder Scale, which depicts a 9-step ladder whose bottom rung is labelled "worst job I could expect to have," and whose top rung is denoted "best job I could expect to have." Respondents select the rung that best describes their feelings about their job. The second measure asks "if you had the chance to start your working life over again, would you choose the same kind of work as you are doing now?" Responses may be made along a subjective likelihood continuum, or simply recorded verbatim for later categorization by coders along a satisfaction continuum. While these simple items may suffice to identify relative differences in satisfaction, accurate assessment of the absolute level of satisfaction is generally recognized as requiring complex instruments such as the Job Description Index (Smith, Kendall and Hulin 1969). The latter in particular has been impressively developed and validated by its authors.

Other measurement strategies in job satisfaction involve (1) inferring satisfaction from measurements of its presumed causes, (2) semi-structured interviews, and (3) recall of critical incidents. The inferential approach (Porter 1962) measures satisfaction as the inverse of the sum of discrepancies between how much of each job aspect an employee feels he is getting and how much he thinks he should be getting or how much he ideally wants. The semi-structured interview approach, while less efficient and objective than other approaches, has much to commend it; Locke (1974) encourages its wider use in satisfaction assessment. Finally, the critical incident recall method developed by Herzberg et al. (1959) is less useful as a measure of how much satisfaction was experienced than as an indicator of the sources of those feelings.

Marital Satisfaction

Marital satisfaction has received considerable attention from home economists and family sociologists. While simple "very satisfied" to "very dissatisfied" self-report rating scales have been used, there is widespread use of multi-item instruments of varying degrees of sophistication. Perhaps best known are the Blood and Wolfe (1960) Marital Satisfaction Index and the Locke and Wallace (1959) Marital Adjustment Test. The former is a four-item scale involving evaluations of the major domains on married life using a fully anchored, five-point affective response

scale, ranging from "pretty disappointed" to "enthusiastic, couldn't be any better." The majority of measures of marital satisfaction involve self-reports, though some are relatively indirect. A review of these measures (e.g., see Straus 1970) reveals considerable variability in the method of measure construction, including a variety of Likert-type summated rating scales, Guttman Scales, and judges' ratings of responses to unstructured projective questions. Noteworthy of marital satisfaction measurement is the common practice of obtaining an individual's evaluation of and affective responses to various component areas of marriage, e.g., spousal understanding, love and affection, companionship, etc., and combining these into an overall measure. Also evident is the attention given to considerations of measure reliability and validity (e.g., Rollins and Cannon 1974).

Patient Satisfaction

Research on patient satisfaction with health care delivery has been recently reviewed by Swan and Carroll (1979). Many investigators in this area have developed their own ad hoc measures which are often simplistic "satisfied--dissatisfied" self-report single item rating scales, either with the overall health care received or with a few selected aspects such as physician attitude, professional competence, convenience, etc. Noteworthy, however, are several major efforts to develop measures based on standard psychometric methods of attitude scale construction. Hulka et al. (1970) used Thurstone's Method of Equal Appearing Intervals for Scaling Attitudes toward physicians, but in a follow-up study (Zyzanski et al. 1974), the researchers revised the scale to a summated Likert-type to obtain improved internal consistency. The content of the 42-item scale suggests that it measures generalized satisfaction with the overall domain of primary health care rather than evaluation of a specific experience. In a similar effort, Ware and Snyder (1975) developed an 80-item Likert summated scale which has found application in several other patient satisfaction studies. One of the 4-item subscales of this measure is termed "general satisfaction" and is reported to have an alpha internal consistency of .77. Again, however, this measure is a highly generalized satisfaction indicator. Finally, Mangelsdorff (1979) developed a 19-item scale for measuring patient satisfaction with a specific health care service received. Individual satisfaction ratings for various aspects of the service are made on a five-point scale and cumulated into an overall index score. The scale has demonstrated high internal consistency and some degree of validity.

Life Satisfaction

One recent sociological study of the perceived quality of life has resulted in perhaps the most sophisticated satisfaction measure development procedures to date. Andrews and Withey (1976) identified a large number of alternative satisfaction measures, which they broadly categorized according to the perspective of evaluation (absolute vs. relative, long range vs. short range), generality (general vs. specific focus), and range (full-range of experiences vs. part-range). In the category of absolute, general, full-range measures, which are of most direct relevance to this review, a number of distinct rating scales measures were examined, including a 7-point "completely satisfied--completely dissatisfied" item, a 7-point fully anchored "Delighted-Terrible" item, and a variety of graphic or non-verbal items. The latter included the self anchoring Ladder Scale previously noted, along with the Faces Scale (Kunin 1955), the Thermometer Scale (warm to cold feelings), and the Circles Scale, which is comprised of nine circles each containing some proportion of pluses and minuses to indicate the incidence of favorable and unfavorable evaluations. In a comprehensive measure evaluation and validation effort, Andrews and Withey concluded that the Delighted-Terrible Scale was the most useful, yielding high

construct validity (estimated at .8), reasonably symmetrical response distributions, and ease of use. The Circles and Faces scales were ranked second on these criteria, followed by the Ladder and Simple Satisfaction scales. The authors suggested that selected combinations of these single item measures might profitably be employed as indexes yielding even higher validities.

Andrews and Withey also evaluated two other types of measures of interest, a Social Comparison rating, in which respondents assessed their satisfaction with life vis a vis other persons they knew, and a Peer Rating, in which three other persons' ratings of an individual's life satisfaction were averaged. Interestingly, neither of these measures attained appreciable validity coefficients and were not recommended for life satisfaction assessment.

Implications for Consumer Satisfaction

The satisfaction literatures in each of the above disciplines reflect three principal common elements: (1) the development of diversity of methods for measuring the construct; (2) widespread use of multiple item scales or index measures; and (3) consistent attention to issues of measure evaluation and validation. Consumer satisfaction research would be well advised to adopt similar measurement traditions. Many of the specific approaches to measuring satisfaction with job, spouse, health care, or life enumerated above also appear potentially suitable for application to product satisfaction assessment.

Job satisfaction measurement suggests the usefulness of two particular kinds of single-item rating scales: the self-anchoring Ladder Scale and the graphic Faces Scale. In addition, the value of a "behavioral tendency" item, in which the respondent's predisposition to repeat his previous behavior is assessed, seems apparent. Less direct self-report measures, particularly the inferential measures in which the extent to which disparities exist between desired outcomes and actual outcomes, also appear to have application. Finally, Locke's (1974) recommendation that open-ended interview data supplement the ubiquitous rating scale, is deserving of further consideration of consumer satisfaction researchers. In fact, Miller (1976) has previously advocated the use of free response formats.

Though not unique to marital and patient satisfaction research, measurement in these areas is often characterized by multi-item scales created by summing evaluations dealing particular aspects of the phenomenon. This approach might be fruitfully applied in the assessment of product/service satisfaction, provided that agreement can be reached on the basic aspects or outcomes involved in consumption. A start in this direction is the distinction between expressive and instrumental product outcomes (Swan and Combs 1976).

Life satisfaction research, in addition to providing an excellent model for measure validation studies, suggests the value of the Delighted-Terrible scale for a wide range of satisfaction assessment applications. Also promising is the Circles graphic scale. Both these rating measures were shown to be superior to simple "satisfied--dissatisfied" overall rating scale items typical of consumer satisfaction research. Life satisfaction studies also suggest the importance of temporal perspective for consumer research, which is rarely considered in the assessment process.

The Study

To appraise the suitability of selected measures from other disciplines in the assessment of consumer satisfaction with specific products and services, the authors undertook a

pilot study whose preliminary results are presented below. This effort is part of a broader investigation currently in progress to develop and evaluate improved indicators of satisfaction with products and services.

Measures

Five types of measures were considered in this study, all rating scale variants. The first is a three-item verbal scale (hereafter VERBAL) combining separate overall assessments of product satisfaction using the Delighted-Terrible 7-point rating scale, a "Completely Satisfied--Not at all Satisfied" 11-point rating scale ranging from 100% to 0%, and a behavioral tendency 11-point rating scale ranging from "Certain I'd do it again" to "No chance I'd do it again." The specific items constituting the overall scale, which can be found in Andrews and Withey (1976, Appendix A), were combined additively to product verbal. These items and all others discussed subsequently are available on request from the authors.

In contrast to the verbal orientation of the first measure, the second involved four distinct graphic rating scales: Faces, Thermometer, Circles, and Ladder. These particular items represent a desirable mixture of nonverbal content. The faces and thermometer scales are chiefly affective, while the Circles and Ladder are more cognitive-evaluative in tone. They were combined additively to yield the overall graphic scale (hereafter GRAPHIC). As before, these items can be found in the Andrews and Withey Appendix and are available from the authors.

The third measure was a Likert summated scale (hereafter LIKERT) in which 12 statements indicating varying sentiments of overall satisfaction with the product were presented to respondents for their agreement. Responses were made on a five-interval "strongly agree--strongly disagree" continuum.

The fourth measure consisted of a set of seven semantic differential items, again dealing with various means of expressing overall satisfaction judgments. To reduce the cognitive strain on respondents only five intervals were used on the semantic differential instead of the conventional seven. These items were combined into a simple additive index (hereafter S-D) after scoring responses as to their favorability.

The final measure was intended as an inferential satisfaction instrument. For each of a variety of product attributes, it assessed (a) the level currently provided by the product and (b) the level ideally desired by the consumer. A difference was computed between each of these ratings and summed over all attributes. This "disparity" figure was presumed inversely related to the level of satisfaction experienced. This scale was termed the PORTER scale.

Sources of Data

Self-administered questionnaires were completed by upper-level undergraduate students at the University of Arizona ($N_1 = 68$) and Washington University ($N_2 = 107$). Cooperation was voluntary and anonymous in both cases. The Arizona sample was surveyed in-class and all subjects agreed to participate. The Washington University survey was to be completed out-of-class; 82% of the students returned their questionnaires. Completion of the instrument took approximately 30 minutes. Respondents were questioned about their experiences with two products currently owned, automobiles and hand-held calculators. Data were analyzed separately by sample.

Results

Descriptive statistics for each measure as applied to each product are shown in Table 1. Ideally the distribution of a satisfaction measure should exhibit a high level of dispersion of responses, thus avoiding "clumping" of respondents within a narrow range of scores. At the same time, a reasonably symmetrical distribution shape is also desired. Examination of the standard deviation of each measure reveals that the LIKERT Scale achieves the greatest dispersion of individual scores for both products, in both samples. The skewness statistics indicate that the VERBAL and LIKERT measures achieve the most symmetrical distributions for automobiles, while for calculators it is the GRAPHIC and LIKERT measures.

TABLE 1
Simple Descriptive Statistics for Satisfaction Measures

Measure	Product	Sample	Mean	S.D.	Skew
VERBAL	Auto	I	17.6	5.7	-.60
		II	19.4	5.0	-.78
	Calc'tr	I	20.3	4.8	-1.62
		II	19.8	5.1	-.58
GRAPHIC	Auto	I	23.8	5.0	-1.22
		II	24.6	4.8	-.59
	Calc'tr	I	19.9	1.4	-.39
		II	24.4	5.6	-.77
LIKERT	Auto	I	40.3	12.1	-1.19
		II	44.8	8.8	-.51
	Calc'tr	I	43.3	6.1	-.95
		II	43.9	9.4	-.70
S-D	Auto	I	22.0	5.5	-1.44
		II	22.8	5.8	-.64
	Calc'tr	I	23.1	4.9	-1.44
		II	21.5	6.8	-.72
PORTER	Auto	I	-10.1	7.0	.81
		II	-9.6	4.9	-1.01
	Calc'tr	I	-4.2	4.5	-1.20
		II	-5.0	4.7	-1.44

Note: Sample I refers to Arizona ($N_1=68$);
Sample II refers to St. Louis ($N_2=107$).

The reliabilities of the various measures as estimated by their internal consistencies are shown in the diagonals of the multitrait-multimethod matrices of Tables 2a and 2b. For the various automobile satisfaction measures, the LIKERT and S-D Scales both attain very high alpha coefficients in both samples, exceeding .93. The VERBAL Scale reliability is also satisfactory in both samples, $\alpha = .72$. In contrast, the PORTER Scale had the lowest internal consistency of all measures in both samples ($\alpha = .68$ and .46). For calculators, the highest internal consistency is attained by the GRAPHIC, LIKERT and S-D Scales, while the others yield somewhat lower though roughly equivalent reliabilities.

Campbell and Fiske's (1959) criteria of convergence and discriminability represent necessary though not sufficient conditions for measure validation. Convergence is demonstrated by high correlations between alternative measures within a given trait. Tables 2a and 2b indicate that there is a high level of convergence among satisfaction measures for automobiles with the exception of the PORTER Scale, which in both studies failed to correlate highly with all

of the other measures. With regard to calculators, all measure intercorrelations are significant, although there is some variability in the strength of the relationships. In contrast to the automobile ratings, the PORTER Scale does indicate convergence with the other satisfaction measures when applied to calculators.

Discriminability also requires that different measures of different traits not correlate. In Sample I (Table 2a), none of the heterotrait-monomethod correlations and only two of the 20 heterotrait-heteromethod correlations reach significance. The significant trait-method pairs are the VERBAL--PORTER and the LIKERT--PORTER.

In Sample II (Table 2b), none of the heterotrait-monomethod or heterotrait-heteromethod correlations reach significance. In addition to the lack of convergence displayed by the PORTER Scale for automobile satisfaction, its lack of convincing discriminability opens its validity to question.

Conclusions

The results of this pilot study suggest that selected satisfaction measures derived from parallel disciplines may have merit as indicators of the level of consumer satisfaction, thereby warranting further attention by researchers in this area. Perhaps most importantly, however, the results also provide much needed evidence as to the validity of satisfaction measures for products and services. Overall, the various multi-item rating scale measures examined in this study appeared to perform reasonably well. All but one of the measures (PORTER) clearly met Campbell and Fiske's (1959) criteria of convergence and discriminability and, in addition, attained high levels of internal consistency reliability. The foregoing, however, may be viewed as necessary though not sufficient conditions for inferring measure validity. Further analysis of the multi-trait-multimethod matrix based on path-analytic conceptualizations and confirmatory factor analysis would be helpful by providing specific estimates of proportions of valid (i.e. trait) variance and correlated errors (i.e. method) variance.

While it is not appropriate to attempt to identify a single "best" measure given the limitations of the samples in this pilot study, the LIKERT, S-D, and VERBAL measures appear promising for automobile satisfaction measurement. Their internal consistency is high, they converge with other measures, and they succeed in discriminating between unrelated constructs; at the same time, they also yield fairly symmetrical, dispersed distributions of individual responses. The shorter length of the VERBAL Scale (3 items) makes it attractive from the standpoint of administrative efficiency. For calculator satisfaction, however, the VERBAL Scale does not appear particularly as promising as LIKERT and S-D measures. Whether this finding indicates that different classes of products or services may require different methods of measurement or whether it simply reflects the vagaries of a small pilot test must await further data collection and analysis.

Perhaps the most problematic of the measures studied was the PORTER Scale, an inferential satisfaction measure based on a summation of disparities between product outcomes and those ideally desired. Its lack of convergence for automobiles is troubling, and suggests that not all of the relevant product outcomes may have been identified for inclusion into the scale. Of course, this potential limitation is not necessarily unique to the PORTER Scale, but rather applies to all attribute-based composite satisfaction measures.

TABLE 2a
 Sample I - Multitrait Multimethod Matrix:
 Satisfaction Measures for Automobiles and Calculators

Method		VERBAL		GRAPHIC		LIKERT		S-D		PORTER		
		Auto	Calc	Auto	Calc	Auto	Calc	Auto	Calc	Auto	Calc	
VERBAL	Auto Satisfaction	(.88)										
	Calc Satisfaction	-.28	(.68)									
GRAPHIC	Auto Satisfaction	.80 ^a	-.21	(.72)								
	Calc Satisfaction	-.27	.39 ^a	-.25	(.90)							
LIKERT	Auto Satisfaction	.87 ^a	-.31	.71 ^a	-.16	(.96)						
	Calc Satisfaction	-.29	.69 ^a	-.29	.46 ^a	-.25	(.75)					
S-D	Auto Satisfaction	.77 ^a	-.19	.69 ^a	-.12	.91 ^a	-.24	(.95)				
	Calc Satisfaction	-.15	.67 ^a	-.15	.41 ^a	-.06	.78 ^a	-.22	(.91)			
PORTER	Auto Satisfaction	.17	-.11	-.06	.12	.15	-.17	.23	-.28	(.68)		
	Calc Satisfaction	-.33 ^a	.55 ^a	-.28	.32 ^a	-.36 ^a	.57 ^a	-.22	.63 ^a	-.08	(.70)	

NOTE: Parenthesized values represent reliability estimates (Cronbach's alpha). Correlations between automobile satisfaction measures are based on N=58 or 59 (difference due to item nonresponse). Those between calculator satisfaction measures are based on N=55 to 59, and those between automobile and calculator satisfaction measures are based on N=47 to 51.

^aSignificant at .01 level

TABLE 2b
 Sample II - Multitrait Multimethod Matrix:
 Satisfaction Measures for Automobiles and Calculators

Method		VERBAL		GRAPHIC		LIKERT		S-D		PORTER		
		Auto	Calc	Auto	Calc	Auto	Calc	Auto	Calc	Auto	Calc	
VERBAL	Auto Satisfaction	(.76)										
	Calc Satisfaction	-.10	(.52)									
GRAPHIC	Auto Satisfaction	.82 ^a	-.08	(.87)								
	Calc Satisfaction	-.15	.84 ^a	-.10	(.93)							
LIKERT	Auto Satisfaction	.87 ^a	-.10	.79 ^a	-.13	(.93)						
	Calc Satisfaction	-.06	.87 ^a	-.01	.78 ^a	-.02	(.95)					
S-D	Auto Satisfaction	.86 ^a	-.11	.82 ^a	-.17	.88 ^a	-.05	(.94)				
	Calc Satisfaction	-.03	.83 ^a	.02	.81 ^a	-.02	.90 ^a	-.02	(.95)			
PORTER	Auto Satisfaction	.32 ^a	-.10	.47 ^a	.01	.27 ^a	-.02	.29 ^a	.04	(.46)		
	Calc Satisfaction	-.05	.65 ^a	.03	.63 ^a	-.08	.67 ^a	-.02	.68 ^a	.08	(.72)	

NOTE: Parenthesized values represent reliability estimates (Cronbach's alpha). Correlations between automobile and calculator satisfaction measures are based N=101; those between automobile and calculator satisfaction measures are based on N=95.

^aSignificant at .01 level

This research has focused on more or less explicit rating scale methods for satisfaction measurement. Overall, these measures have been observed to work reasonably well in two separate samples. Future research comparing these methods to less structured methods of measurement, notably those based upon open-ended questions, would be especially helpful. Such data realistically will require collection by personal or telephone interview rather than self-administration. However, as Locke (1974) has argued in the context of job satisfaction research, they may provide considerably deeper insight into the meaning of consumers' evaluation and sentiments. Andreassen (1977) has indicated that consistently lower estimates of satisfaction are obtained from free-response data. Which measurement technique is the more accurate indicator of consumer satisfaction, however, remains a question for further research.

HIERARCHICAL COGNITIVE CONTENT: TOWARDS A MEASUREMENT METHODOLOGY

Elizabeth C. Hirschman, New York University
Susan P. Douglas, New York University

Introduction

In recent years increasing interest has arisen in developing methodologies for measuring cognitive phenomena. In particular, growing use has been made of information processing approaches to understand consumer decision-making (Bettman 1980), product perception (Olson 1978) and attitude structure (Capon and Lutz 1979). Attention has thus been drawn to identifying what information relating to products is used by consumers, and how that information is organized in memory.

Research has focused primarily on examining product attribute information, and on assessing how this is used in evaluating brands and products. Use has been made of protocol techniques (for a summary see, Douglas, Craig and Fairre 1980), or less commonly free recall prompted by an external cue or cover story (Russo and Johnson 1980, Olson and Muderrisoglu 1977). This research has, however, largely ignored the broader semantic network surrounding the product, namely product-variant linkages to form categories or product classes and brand-product hierarchical linkages to form general to specific orderings of content (Lachman, Lachman, Butterfield 1979).

One exception to this is the work of Gutman (1980) which has explored the broadness/narrowness of categories created by consumers from given product stimuli. The hierarchical character of product-brand-attribute categories has, however been largely ignored.

For example, whether the consumer uses the product-concept primarily as a node (storage area) for accumulating and organizing other types of information, or as an item of knowledge moderating (i.e. qualifying, or describing) a category. Take, for example, the concepts "Levi's" and "jeans". For some consumers, the primary cognitive category is "jeans", for which Levi's is a moderator (i.e. a qualifier). For other consumers "Levi's" is the node (category), and "jeans" is a moderator.

Such information is, nonetheless, of interest to assess how consumers categorize and classify products, product classes, brands and domains, and how this information is maintained in memory. It might also be useful in developing advertising copy, by indicating the scope of the semantic image, i.e. the combinations of products, and brands, which are stored together by consumers.

An issue which arises in this context is the appropriate methodology to examine the hierarchical content of information in memory. This paper reports an attempt to apply free-association techniques to examine cognitive content and, given the limitations of this methodology, to suggest an alternative approach.

Free Association Methodologies

Free response and word association techniques are widely used in cognitive psychology (Rosch 1978) and in cross-cultural research (Szalay and Deese 1978, Rosenzweig 1961) to identify domains, examine product categorization, and the meanings associated with products and objects and to compare these across cultures. Their use in marketing has been somewhat more limited, largely due to difficulties and tediousness of analysis (Green, Wind and Jain 1973).

The advantage of using consumers' free associations to a product concept, as opposed to the multi-attribute approach, is that all types of semantic associations regarding a product can be measured, not just the attributes. Hence, the measurement of consumers' product cognitions is extended beyond attribute structure to the total semantic associational structure.

The free association technique can, for example, provide valuable information about brands perceived as competing. For example, in response to the stimulus brand "McDonalds", responses of "Burger King" and "Wendy's", may be obtained, indicating that these are perceived as similar and hence potential competitors. Similarly, in response to "jeans" the responses "Levi's", "Gloria Vanderbilt", "Sasson" and "Jorache" may be obtained. These, therefore, represent the consumer's evoked set for this product category. Finally, free associations may provide information on the uses to which a product/brand could be put by the consumer. For example, in response to the stimulus product "shoes", associations such as "running", "soccer", "basketball", and "jogging" may be obtained. These show both the degree of differentiation within the product category perceived by the consumer and also the possible activities for which s/he might utilize the product (i.e. shoes).

Extension to a Cognitive Hierarchy

Free association techniques have been widely used in psychology to examine the hierarchical structure of information content. This perhaps best exemplified by the work of psychologist Eleanor Rosch. Rosch (1973, 1974, 1975, 1978) maintains that concepts may be arranged along a continuum from abstraction/generality to concreteness/specificity. Three levels along this continuum are identified: (1) a superordinate level of the most general or abstract concepts (e.g. furniture), (2) a basic level of more concrete/specific concepts (such as chair) and (3) a subordinate level of most concrete/specific concepts (such as dining room chair).

Rosch has focused primarily on studying horizontal categorization at each level of the category by asking respondents to indicate attributes associated with the level. Here, a key finding has been that the number of attributes associated with a concept decreases as a function of generality. Thus, fewer attributes are cited at higher levels of abstraction in the hierarchy. This does not, however, imply that the total number of cognitive associations is lower for more general concepts. Rather the character of these associations changes, with concrete nouns instead of attributes being associated with more general concepts.

This was demonstrated in consumer research by Hirschman (1980). Free association techniques revealed no relation between the absolute number of word associations to a product and its level in the hierarchy. Four levels were examined: domain-level, (entertainment), type-level (movie), generic-level, (adventure Movie) and brand-level (James Bond movie). The associations made at the general domain level (entertainment) tended to be predominantly concrete nouns (e.g. a movie); whereas the associations made at the specific generic and brand levels were more likely to be descriptive qualifiers and attributes (e.g. soft, delicious). This is shown in Table 1. Thus, use of a free response word association approach not only confirms

TABLE 1

	Cow (21)	Creamy (13)	
	Ice Cream (19)	Flavors (12)	

Rosch's finding that more attributes were associated with more specific concepts, but also demonstrated that different types of associational content (e.g. nouns were associated with different levels.

The use of a free association approach in examining hierarchical cognitive content has, however, some disadvantages. One inherent disadvantage of free association data are that they provide no information on the nature of the association, and, in particular, on the propositional relationship of an evoked response to the product stimulus. For example, does the association of "sneaker" and "running" mean that a sneaker is seen as a running shoe, or that sneakers are used in running?

A further disadvantage is that a stimulus list (i.e. set of product/brand names) has to be developed a priori and arranged in a specific hierarchy. For example, in one experiment, the following hierarchy was selected: Apparel, Pants, Jeans, and Levi's Jeans. This set was then presented (along with several other sets in randomized order) to the respondent and words associated with each level were recorded. In analyzing the data, it was assumed that this provided an appropriate general-to-specific ordering.

This assumption, although it appears logical and possesses "face validity" may, however, not be appropriate for some or all consumers or for some or all product classifications. A final, and perhaps most critical limitation of the free association technique in studying cognitive hierarchies, was that the associations tended to be predominantly horizontal rather than vertical. This was particularly the case in relation to the more specific concepts where modifiers were commonly provided. Consequently, while it has initially been hoped to capture more of the vertical semantic network surrounding the concepts, this was only partially achieved, with the stimulus set used.

The Hirschman-Douglas Card Sorting Task

Given the limitations of the word association task, an

alternative procedure was developed for examining hierarchical cognitive structure. This procedure, termed the Hirschman-Douglas Card Sorting Task (or H-D CST), consists of listing on cards the names of products/brands hypothesized to represent different levels of generality-specificity in a given consumption domain. These cards are then given to subjects who are asked to sort them into piles or groups based on perceived similarity.

In a trial experiment of this method, subjects were provided with six product concepts from two of three different consumption domains (e.g. food, clothing and entertainment). The six product concepts within each domain were selected a priori from three hierarchical levels: Type (television, meat), Generic (talk show, hamburger), and Brand (Johnny Carson, McDonalds). Five pairs of adjectives or modifiers were also included. Three of these were the pairs found by Csgood to be universal qualifiers of meanings (Csgood, May and Miror, 1975). Two more product specific adjectives, i.e. cheap/expensive, and hard/soft, were added. Thus, the subject was given a total of 32 cards representing products/brands from two different consumption domains and five pairs of adjectives. A complete listing of all stimuli is given in Table 2.

In performing the task, subjects were instructed first to look at the cards and then arrange them into "groups that make sense to you" or "piles of things that are closest." Subjects were told that they could make as many or as few groups as they wanted and that there was no time limit and no right or wrong answer to their response. Half of the subjects were required to perform the task twice, being presented first, with one combination of two domains e.g. food and clothing and then another, e.g. food and entertainment. These were systematically rotated to test for order or domain effects.

A convenience sample (n=40) was used for the trial experiment and subjects were drawn from a variety of socioeconomic backgrounds: students, secretaries, guards, professors, businessmen and so forth. The sample is, therefore, not representative of any population. It does, however, provide sufficient variety to make some comments on the methodology.

The first general observation is that the task elicited a high level of involvement and interest on the part of the subjects. In contrast to the disinterest and fatigue often displayed by subjects responding to a questionnaire, the card sorting task generated enthusiasm. The majority of subjects stated that they found the task to be "fun" and "interesting" and completed it in five to fifteen minutes. Thus the recruitment and involvement of subjects does not appear to be a problem with this particular data-gathering technique.

Results

These data were then analyzed by three judges to identify the patterns used by subjects in categorizing the stimulus set. Two major dimensions were identified: 1) whether subjects organized the cards vertically or horizontally, and 2) the degree of tightness, complexity or order subjects used to form the groupings. A high degree of reliability was obtained in the analysis, -disagreement arising in only 5 out of 60 cases.

A key finding is that many people do appear to use a hierarchical framework in organizing their knowledge within consumption domains, though not the tidy and neat structure assumed by the Rosch model. The majority, of subjects (80%) recovered the hierarchies in the stimulus set. They differed, however, in the extent that to which they added adjectives or pairs of adjectives to qualify hierarchies (Figure 1).

FIGURE 2

A VERTICAL BRAND-ORDERED PATTERN

A HORIZONTAL ORDERED PATTERN

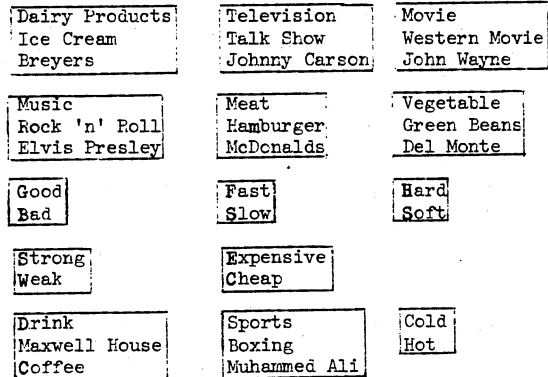

FIGURE 3

A VERTICAL TYPE ORDERED PATTERN

Some subjects (19%), particularly those who expressed low involvement with the stimulus set, grouped the cards into three piles - adjectives, brand names and products (Figure 2).

Another aspect was how the hierarchies were organized. Some subjects adopted a predominantly brand-organized structure. For example, in Figure 1 the groupings are all headed by a brand-level concept. Others adopted a type-level structure. This is shown in Figure 3. Within each grouping the Rosch-like hierarchical structure is maintained (i.e., Type, Generic, Brand) with only one interesting exception: drink, Maxwell House, coffee. Some subjects declared themselves unable to order within piles. This occurred primarily when somewhat complex structures were developed initially.

The other dimension - tightness vs. looseness - refers to how highly organized the structure created by the subject was. A very "tight" structure was one in which all the cards were grouped into a maximum of three piles (10%) (Figure 4). This occurred predominantly where subjects appeared to have a strong need for order. 16% had a moderately tight structure i.e. four to five piles. The majority (73%), adopted a loose structure in which several cards were grouped into pairs (representing a two-level, or binary hierarchy) and/or were left unrelated to one another (that is, were "grouped" as individual units).

FIGURE 4
A TIGHT STRUCTURE

Underwear	Music	Cheap
Bra	Rock and Roll	Expensive
Playtex	Elvis Presley	Hot
Pants	Sports	Cold
Jeans	Boxing	Bad
Levis	Muhammed Ali	Good
Coat	Movie	Weak
Raincoat	Western Movie	Soft
London Fog	John Wayne	Hard
Shoes	T.V.	Slow
Sneakers	Talk Show	Fast
Adidas	Johnny Carson	

A critical assumption underlying this procedure is that the groupings created by the subject with the cards correspond to the way information is structured in his/her memory. Whether this assumption is valid or not remains open to some question. However, subjects did not appear to have any difficulty with the task, or find it artificial, and the differences in the resulting structures suggest that the assumption may be appropriate.

It should be noted that the card sorting task methodology is still in the early stages of development. Further work in devising appropriate stimulus sets is required. The stimulus hierarchies were arbitrarily defined by the researchers and imposed on the subject. It is therefore difficult to assess how much of the structure obtained is a result simply of the specific stimulus set. One alternative which might partially eliminate this bias is to provide the subject with a more ambiguous and complex set of words from varied domains of consumption. If the task is repeated for several domains the consistency of organizational patterns can be examined. Furthermore, the same set of words can be given at various time intervals to measure the stability of response.

The card sorting task may not be appropriate for all consumers. Tests conducted with a number of children indicated that children do not respond to the stimuli in the same way as adults. Children, for instance, tended to respond to the words not as representing products, but rather as semantic entities. For example, a typical child's approach to sorting the cards is to alphabetize the words, or to group them into piles according to word length, number of words on the card, and so forth.

This is consistent with studies of cognitive development (Gelman 1978) which indicate that younger children are unable to reason abstractly using semantic stimuli or handle hierarchical classification, because they have not arrived at the level of what Piaget terms symbolic operations (Piaget 1976). Hence, they do not perceive the words as representing products, but rather as semantic entities.¹

¹The card sorting task may be similarly inappropriate for psychometricians, consumer researchers and marketing model-builders. For example, one well-known marketing model-builder who, while complaining that it was trivial and meaningless, proceeded to construct a geometric con-

Additional Applications of the Free Association and Card Sorting Techniques

Free Association

The type of free association techniques discussed here also have a number of other potential applications. Perhaps one of the most valuable applications is in the area of subcultural and cross-cultural consumer research (Wind and Douglas 1980). The free association approach is essentially an unstructured and hence predominantly emic method for data gathering and analysis (e.g. Szalay and Deese 1978, Pike 1966, Ember 1977, Triandis 1972).² It does not imply the imposition of a construct identified in one culture on another culture, where it may not be relevant. Rather it allows consumers in various cultures or subcultures to respond freely in their own terms with whatever verbal or written signs they feel most appropriate.

Some cultural self-referent bias (Lee 1966) may however be introduced by the researcher given his specific cultural referent in the choice of the stimuli and in interpretation of the data. Hence, careful attention to "decentering" the stimulus set will be required (Werner and Campbell 1973). In addition, since the onus of interpretation is placed on the researcher in determining where there are similarities and differences between countries, use of multiple judges from different cultures will be desirable.

One potential use of free association data in this context is to compute "shared meaning" (i.e. similarity) ratios between cultures or subcultures, or to identify to which culture or subculture a consumer belongs (Szalay and Deese 1978). If the same or similar responses are associated with the same product, the cultures may be classified as similar (Hirschman 1980). Additionally, where consumers belong to more than one subculture, for example, a Jewish American teenager, the associations made in relation to a particular product will indicate which subculture dominates in relation to that particular product.

The methodology can also be extended to examine the meaning attached to different colors, shapes or to composite objects in different cultures and countries (Deregowski 1980, Pick 1980). Consumers could, for example, be given a set of colors or shapes and asked to provide associations to them. Similarly more complex stimuli sets such as actual products and brands could be used.

figuration atop his desk with precise euclidean distances separating the cards. Unfortunately, the author-administrator neglected to copy down the resulting multi-dimensional cognitive map. On the other hand, perhaps we are better off left in ignorance.

²The "emic" and the "etic" distinction is an important one in cross-national and cross-cultural research (Ember 1977, Pike 1954, Triandis 1972). The "emic" school holds that attitudinal or behavioral phenomena are expressed in a unique way in each culture, and are best understood in their own terms. Following this point of view, measures specifically adapted to each cultural context will be required. The "etic" school, on the other hand, is primarily concerned with identifying universal or "culture-free" measures. This facilitates comparisons but potentially leads to loss of some precision or accuracy of measurement in each national context (Elder 1976, Przeworski and Teune 1966/7, 1970).

Such procedures might also be appropriate to study children's responses to products, brands and advertisements. Since small children have difficulty grasping abstract concepts, use of visual stimuli may aid considerably in increasing comprehension.

Card Sorting

The card sorting task would also appear to have potential applications in cross-cultural and subcultural research. Again, the same caveats apply as for the free association task in that care must be taken to avoid a pseudo-etic bias in the design of the product set and in its interpretation. In many cases it may be desirable to include in the set, products specific to a particular culture, as well as those common across cultures.

If a set of products common across cultures is identified, the card-sorting task may be used to assess whether certain cultures are characterized by predominantly product-type, brand-type or other cognitive organization structures. The level of advertising may, for example, affect information organization. The relative looseness or tightness of the organizational pattern and complexity of organization also may vary across cultures depending upon the level of education or societal development.

As in the case of free association techniques, the Hirschman-Douglas sort task can be extended by using more complex stimuli. These might, for example, include use of black and white or colored pictures and photographs of products and brands or actual objects. Consumers would then be requested to sort these into piles based on similarity, and differences and similarities in these patterns between cultures and countries could be examined. Again, the technique might be highly appropriate with children.

Finally, both the free association and card-sorting tasks may be used to examine the relation between cognitive structure and respondent characteristics. The number of responses given to a stimulus product may be related to high levels of cognitive complexity and intelligence. The tightness and complexity of the organizational pattern may also reflect intelligence and cognitive complexity, and may be related to such personality traits as desire for closure and tolerance of ambiguity. Other factors such as media usage patterns and relative level of information seeking may also relate to cognitive structure and, hence, to a consumer's performance on both the free response and card-sorting tasks.

Conclusions

The purpose of this paper is to suggest the use of two approaches - free association and card sorting - in investigating hierarchical cognitive content. These approaches provide a useful extension to the type of information obtained from traditional approaches. In particular, they may aid in extending knowledge of the content and structure of consumer product cognitions and information storage and have potential applications in cross-cultural and cross-national research.

The results of the present experiment indicate that the majority of subjects organize the stimulus set into hierarchies, generally of more than five groups. The test re-test reliability of this finding was also high, indicating stability in results, and specific that the patterns obtained were not specific to a particular product class. The patterns may however in part due to the nature of the stimulus set, although alternative groupings were feasible.

It should, however, be noted that both approaches, and in particular, the card sort task, are still in the early stages of development. Considerable further work in

refinement of the method, particularly with regard to the development of the stimulus set, notably a more ambiguous set and appropriate analytic procedures will clearly be required. Furthermore, adaptation relative to specific research objectives is also needed.

USAGE-SITUATIONAL INFLUENCES ON PERCEPTIONS OF PRODUCT-MARKETS:
THEORETICAL AND EMPIRICAL ISSUES

Rajendra K. Srivastava, University of Texas at Austin

Abstract

Cognitive approaches for the modeling of consumer choice and product-market structures have generally been based on the perspective where product-markets may be defined as consisting of those products that are purchased by the same consumers who presumably desire the same benefits/costs that products may offer. However, products and consumers are embedded in an environment which may influence choices. This paper reviews the affect of environmental (in particular, usage-situational) conditions on perceptions of product-markets and raises a number of research issues.

Introduction

Deterministic brand preference/choice models are generally based on the premise that products are valued for the attributes they possess and that customers seek to maximize their "utility" by choosing/purchasing desired combinations of attributes. Thus products/brands offering similar combinations of (levels of) attributes are likely to be more substitutable/competitive. This perspective is widely maintained in consumer/marketing research as evidenced by the formulation of multi-attribute attitude/preference models (see Wilkie and Pessemier 1979) and associated methodologies such as perceptual mapping (see Shocker and Srinivasan 1979). These models/techniques portray differences in preference among consumer segments by means of their objectives (ideal-points) and/or trade-offs (importance weights) for the benefits/costs associated with the dimensions of the attribute space. Though the conceptualization is intuitively appealing, the validity of the approach has been questioned by several researchers who have noted the discrepancy between attitude/preference and actual behavior/choice.

First, the proponents of the notion that customer choices are the result of multiple stage choice processes (Bettman 1979, Wright and Barbour 1977, and Payne 1976) would contend that the importance weights, and indeed the set of items under consideration for usage or purchase, would depend on the stage of information processing. In the initial stages of information processing, the emphasis is on screening alternatives in order to minimize information overload, there is a tendency for individuals to use lexicographic rules. In subsequent stage(s) there is an increasing tendency to employ compensatory strategies. The implication of this notion is that the attribute weights and ideal points that are derived could be a function of items included in the preference elicitation task (structured by the research) and the subsequent modeling of these data as a single-stage choice process could be misconceived.

Second, there is the contention that the first choice (most preferred item) attitude or preference models used for predicting customer behavior fail to recognize the customers often choose multiple items from a product class. For example, if a subject furnishes a preference ranking of Coke, Pepsi and Seven-up, yet purchases only Coke and Seven-up for consumption, the discrepancy between preference and choice could be explained by the notions of: (1) dominance--Coke dominates Pepsi but not Seven-up on all attributes (see Huber and Reibstein 1977), and/or (2) attribute satiation--where customers

are seen as seeking balance among the attribute levels of a set of items (Farquhar and Rao 1976, McAlister 1979).

Finally, recent research has clearly illustrated the importance of environmental influences in determining consumer choice (Belk 1974, 1979, Srivastava, Shocker and Day 1978, Srivastava 1979, 1980, Kakkar and Lutz 1975). At a conceptual level, situational influences may be seen as moderating the importance of benefits that customers seek. For example, within the broad markets for "beverages," the usage context "at a picnic" may make the attribute "refreshing ability" more salient than in the usage context "after dinner."

The concepts of environmental influences, multiple choice and multistage processing appear to be quite consistent. In the initial stage(s), simplifying strategies may be used to reduce the number of alternatives to be examined at subsequent stages. A customer may first develop consideration sets of products based on their functional attributes, i.e., those characteristics that are in some sense "required" in the environmental context. Subsequently, they may examine this reduced set of alternatives on the basis of attributes still considered important, but along which the alternatives in the reduced set vary in terms of the "level of attribute" present in order to determine their final choice (see the concept of "determinant" attributes--Myers and Alpert 1968). Different environmental contexts are likely to lead to varying consideration sets and consequently multiple choices. Thus, rather than merely contend that customers seek a balance among attributes presumably due to either variety seeking or satiation, an alternative (and perhaps more explanatory) perspective is that environmental requirements dictate the importance of product attributes, and that consumers develop a product portfolio that reflects the set of situations they expect to encounter.

Though environmental influences seem to provide a vital link between preference and choice, there are unfortunately numerous types of such factors that could be relevant (e.g., physical and social surrounding, task definition, antecedant conditions, and temporal perspective; see Belk 1975). This paper attempts to provide a conceptual framework where the purpose of the research, or the decision context within which product market structure is to be used, is seen as moderating the importance of the types of environmental variables.

A Contingency Model For Market Relationships

The derivation of product market structures is dependent on two considerations: (1) the choice of a measure of the degree of competition, or its surrogate substitutability, between products (for example, perceived similarity between product-pairs), and (2) the choice of an appropriate data-reduction technique for analyzing the inter-product similarities (for example, multidimensional scaling, cluster analysis). In their comprehensive review of customer-oriented (based on demand, rather than supply considerations) approaches for identifying product-markets, Day, Shocker and Srivastava conclude that "the suitability of different methods (measure-technique combination) is strongly influenced by the character of the market environment" (1979, p. 18, words within paren-

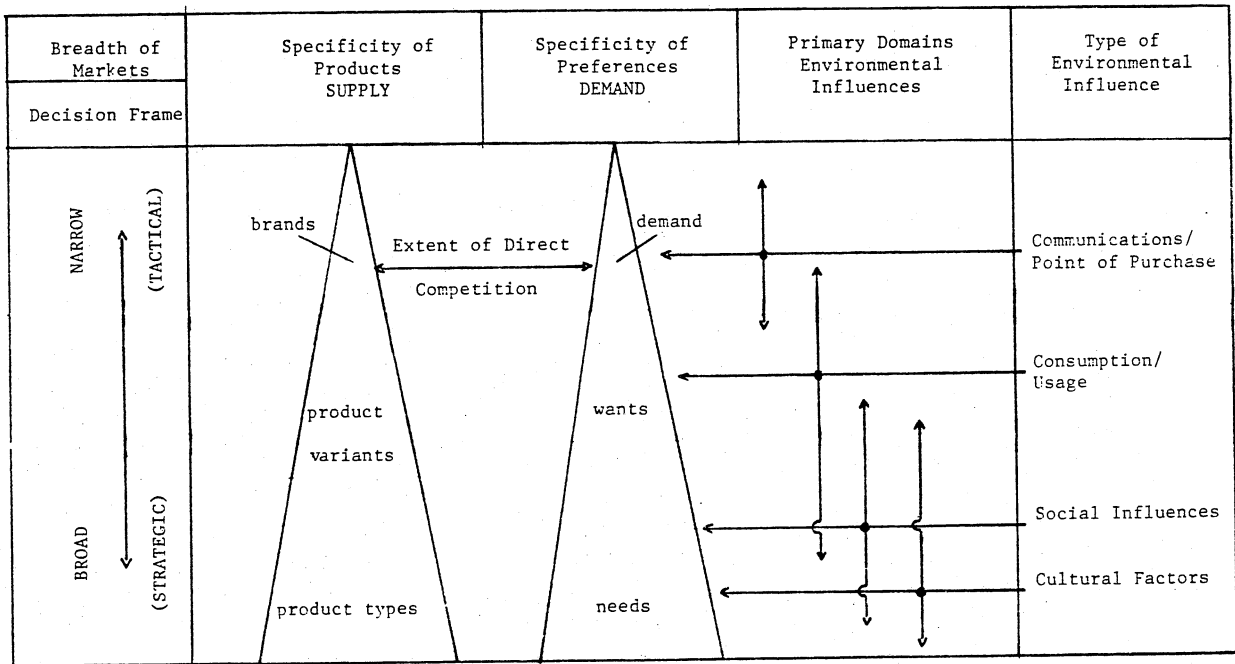

theses, ours). Further they conclude that "the questions of how to identify product-market boundaries cannot be separated from the way results are to be used."

Exhibit 1 presents a framework that relates the market environment (types of environmental influences) and the way results are to be used (strategic versus tactical decisions) to the concept of the product hierarchy (Lunn 1972). This framework is partially adapted from Arndt's (1976) conceptualization of the relationship between competition at various levels (brand, product-variants, product types) of the product hierarchy, specificity of customer needs, and types of situational influences.

as nutritional value and keeping awake. Product-variants are available within the same overall product type and are likely to be more competitive in the short run. For example, ground and instant coffee can be expected to compete more directly. Finally, brands within the same product variant compete even more directly. For example, brands of instant coffee are very similar in the purposes they serve. The specificity of customer preferences may be related to the notion of the product hierarchy via the conceptualization that consumer decision-making may be a hierarchical or multi-stage process where simplifying strategies (rules of thumb) may be utilized to eliminate product types, variants, and brands sequentially. For example, a person considering

EXHIBIT 1

A CONTINGENCY MODEL FOR MARKET RELATIONSHIPS

The "decision frame" (column 1) is related to the breadth of market that is likely to be of managerial interest. Very narrowly-defined boundaries appear adequate for short-run, tactical decisions (Day, Shocker, and Srivastava 1979) for which management is mostly concerned about the current and direct competition from the brands of rival firms. On the other hand, the long-run strategic decisions, management is concerned not only about the current and direct competition from very similar brands but also the potential, less direct competition from other product-variants/types which may be more substantial threats in the future due to changed economic conditions, regulations or shifts in consumer needs. Therefore, for strategic decisions, broader market definitions would appear to be more appropriate.

Columns 2 and 3 reflect the relationship between the levels of the product hierarchy and the specificity of consumer preferences. It must be emphasized that these levels are not discrete but represent points along a continuum such that the extent of direct competition decreases as one comes down the hierarchy (from brands to product categories). Totally different product-types exist to satisfy significantly different purposes in different situations. For example, in the market for hot beverages, coca and coffee may serve purposes such

the choice of a beverage may discard cocoa since his primary objective might be to stay awake, then ground coffee, as it may require too much effort to prepare and finally choose among various brands of instant coffee on the basis of flavor. This example is quite simplistic, yet it serves to illustrate the process that is likely to occur in a more subtle manner.

Though environmental factors influence customer choice, different types of situational factors are likely to affect competition at various levels of the product hierarchy through their influence on the customer choice process (specificity of preference). For example, adopting Hansen's (1972) categorization of the types of environmental influences again considering the beverage example, social influences (peer pressure) and cultural norms may affect the choice between tea and coffee. If the coffee route was chosen, the consumption or usage-situation (e.g., while entertaining guests versus grabbing a quick cup) may determine the choice between instant and ground coffee. Finally, if instant coffee were the chosen route, communication (advertisements, word-of-mouth communication regarding flavor) or point-of-purchase factors (coupons, displays) may influence the choice among brands of instant coffee. This is not to say that the different types of

environmental influences affect discrete levels of the hierarchies. Column 4 depicts the likely domains of influence of the various types of environmental influences (column 5). Further, it is important to realize that the distinctions drawn in the previous paragraphs do not categorically imply, for instance, that cultural factors do not shape brand preferences. Though cultural factors primarily affect competition between product types, their influence at the higher (e.g., brand) levels of the product hierarchy will be indirectly based on: (1) the sequential conversion of diffused goals/preferences into more specific ones, and (2) the dependence of the less stable factors on the more stable ones (for example, cultural norms may determine the relevance of usage-situations as well as the frequency with which they arise for different individuals).

The relationship in Exhibit 1 may appear to represent an "all-encompassing" model of customer behavior and certainly cannot be verified within the scope of a single research. However, scattered pieces of previous research verify portions of the framework. For example, Miller (1975) and Srivastava, Shocker and Day (1978) observe that anticipated usage situations appear not to affect preferences at the brand level.

Perceptions of Product Markets: Research Issues

Response Homogeneity and Deterministic Choice Models

Belk (1979), Srivastava, Shocker and Day (1978) and Srivastava (1979) observe a high degree of response homogeneity among subjects when the effects of the usage-situation are controlled for, while previous researchers which ignore situational influences note the discrepancy between preference and choice ("error variance") as well as the differences among individuals ("heterogeneity"). Some of the error variance and heterogeneity may be due to the fact that choices are situation-specific (while the elicited preferences were not obtained as such), and different individuals may have given their preferences with varying usage or consumption situations in mind. For example, if a respondent is provided several brands of instant and regular coffee and asked to rank order preferences, she/he may do so keeping "flavor" in mind and provide higher ranks to the regular coffee brands. Another respondent may perform the task with "ease of preparation" in mind and provide relatively higher ranks to the instant brands. However, both may actually use instant coffee when in a hurry and regular coffee while entertaining. The above self-serving and somewhat simplistic example illustrates that both error variance and respondent heterogeneity may be attributable to the ambiguity of the response task. Accordingly, as argued by Rokeach and Kliejunas, we must elicit attitudes toward objects within a situation if we are interested in predicting situation specific behaviors (1972).

The adoption of situational influences in consumer choice models is equivalent to contending that the usage situations affect importance weights and/or ideal points (Srivastava 1979, Hagerty 1980, Miller and Ginter 1979, Pekelman and Son 1976). It is much less likely that perceptions of attribute levels would be affected. The specification of the situational variables may be expected to more clearly define the attributes that consumers seek, and further, simplify the judgmental task. Consequently one may expect greater homogeneity between respondents and less error variance. That is, the explicit consideration of situational influences should allow for a more deterministic view of customer behavior (Srivastava 1980). Bass notes that "it will never be possible to prove conclusively that behavior is fundamentally deterministic since it will never be possible to measure all the variables which influence choice"

(1974, p. 2). While it is hard to dispute this statement, the explicit consideration of situational influences enables a more deterministic (and correspondingly more explanatory) view of customer behavior.

Situational Taxonomies

Though this deterministic conceptualization is appealing in terms of its ability to account for discrepancy between preference and choice, the estimation of the distribution of attribute weights remains a very real problem. Additionally, even if the distributions were estimable, we would not know the relationship between attribute weights and different types of situational influence. This kind of understanding is more probable if a taxonomy of situational influences (which enables the explicit, systematic consideration of environmental factors) is developed.

In general, two approaches have been followed in an attempt to develop situational taxonomies. Neither is totally satisfactory. The first has sought to classify situations by the nature of the psychological processes which they lead to. For example, Kakkar and Lutz (1975) attempt to classify situations in terms of Mehrabian and Russell's (1974) dimensions of pleasure, arousal and dominance. The advantage of this approach is that the focus is on the situation as perceived by the individual, and that is parsimonious and general (applies to all product contexts). Unfortunately, the psychological taxonomic dimensions appear to have little systematic effect on preferences (Kakkar and Lutz 1975).

The concept of a general taxonomy of situational influences for the moment, appears unlikely to be realized. This is because situational influences that affect some consumer behaviors (e.g., the choice of "high-involvement" products such as automobiles) could be entirely different from those that affect other behaviors (e.g., the choice of "low-involvement" products such as soft drinks) (Belk 1979). However, product-specific taxonomies based on objective situations (factors external to consumers that may lead to differences in elicited behavior) may be easily constructed by following procedures outlined in Fredriksen's (1972) article and as implemented by Srivastava, Shocker and Day (1978) in the "breath freshener" market and Belk (1979) in the "clothing" market. While the objective taxonomies appear to be better descriptors of consumer behavior compared to psychological taxonomies, they present a major drawback in that situations may have to be defined in great detail to the point where the number of variables is massive enough to make reliable measurement and meaningful analysis impossible (Lutz and Kakkar 1975, Russell and Mehrabian 1976). However, the efforts devoted to developing objective situational taxonomies (Belk 1975, 1979, Srivastava, Shocker and Day 1978, Srivastava 1979) have generally resulted in two or three taxonomic dimensions that are adequate for explaining most of the situational variance.

The key point is that in the creation of situational taxonomies we are interested in those aspects of the environment that affect consumer behavior. Although the total number of situations that persons encounter is enormous, and each situation is unique and the likelihood of exact replication is exceedingly small, it is undoubtedly also true that people do not behave differently under all such changed circumstances. Prior learning and usage experience are integrated into relatively routinized responses (Howard and Sheth 1969) in many of these instances. Many authors have argued that humans have relatively limited capability for processing information and problem solving (see Slovic 1972, Bettman 1979). They develop heuristic or simple rules of thumb that enable them to deal with complex situations. They appear to categorize prior learning and

experience in memory and base choices and decisions on such categorizations (Rosch 1978). Consequently, respondents may evoke similar categorizations or stereotyped uses that are represented in a simple way in memory.

Situational/Lifestyle Segmentation

The apparent homogeneity of consumer response when situational influences are controlled for suggests the possibility of situational segmentation. That is, product-markets and competitive effects can be examined within "situational submarkets". This line of inquiry may lead to interesting research issues as certain situational types are likely to occur with differing frequencies for different consumer segments. Subsequently, the identification of lifestyle, cultural, demographic or other factors which effect the frequency of occurrence of situational types can offer better opportunities for targeting marketing efforts to those people who experience relevant (for use of specific products/brands) with greater frequency.

Measures of Substitutability

Traditionally, marketing researchers have focused their attention towards examining competition between brands, perhaps partially due to the demands placed by the utilizers of research who may be besieged with the more immediate (tactical) decision-contexts. Within these contexts, where narrowly-defined markets (e.g., brands of instant coffee may be adequate, the traditional focus on point-of purchase (display, shelf-level/space) and communication (advertising, promotional activities) influences certainly encompass the primary environmental factors affecting customer choice. Moreover, these brands are likely to be very similar (in terms of physical characteristics/functions served/benefits provided) and are likely to be used for the same usage/consumption situations(s) by the same customers (with similar social/cultural backgrounds). In this context, one cannot question the adequacy of the more familiar measures of inter-product similarity (a surrogate for substitutability) such as: (1) similarity of brand attributes - correlation or "matching" coefficients between brands across attributes, (2) overall perceived similarity - as measured by similar-dissimilar brand-pair ratings (Jain and Etgar 1975) or by sorting brands into groups and subsequently obtaining a similarity measure based on the proportion of times brand-pairs were sorted into the same group (Bourgeois and Haines 1975), and (3) direct measures of substitutability - such as Pessemier's (1975) "dollar-metric" measure or other measures eliciting the degree of substitutability between brand-pairs on a rating scale.

However, when the interest lies in developing market structures for strategic decisions, it is desirable to not only understand the immediate competition (i.e., at the brand level) but also the nature of the competition between product variants/types that may be potentially competitive. When the interest lies in examining the competition between product variants/types, usage-situational influences begin to play an important role because: (1) products may be substitutable under some circumstances (usage situations), yet may not compete under others, i.e., products may have multiple uses which may not overlap completely between product pairs and the appropriateness for use of a product may depend on the "match" between product benefits and the requirements of the usage-situation (Belk 1974, 1979, Steffire 1971, Srivastava, Shocker, and Day 1979), and (2) customers may develop "assortments" or collection of products in order to be prepared to meet the future contingencies across diverse, anticipated usage occasions (Wind 1977).

It would appear from the previous paragraph that for strategic marketing decision-making where broader market structures are desirable, "substitution-in-use" or the similarity of product usage patterns would provide a managerially relevant measure of inter-product substitutability. Further, since product variants/types need not have all attributes (benefits/characteristics) in common, the more traditional measures (e.g., similarity of product attributes) may be "discontinuous" when applied to study competition at the lower levels of the product hierarchy (this problem can be alleviated to some extent by the use of discrete multivariate methods to analyze the data). This does not imply that the more traditional measures are irrelevant but merely that substitution-in-use appears to be better-suited for developing broader market structures. Indeed, it may be useful to adopt a two-stage methodology where substitution-in-use is first used to develop the broader market structure and to identify the discontinuities in this space. Then, within each situationally defined submarket, the traditional measures may be employed to obtain a better understanding of the more direct competitive relationships (Shocker and Srinivasan 1974, 1979). Additionally, if the relative frequencies of taxonomic cells are obtained it should be feasible to predict the assortment of products that individuals are likely to purchase to serve their needs across anticipated usage-situations. As mentioned earlier, this offers an alternate explanation to attribute satiation for modeling multiple choices.

Discussion

Throughout this paper there has been an emphasis on the matchings between situational requirements and product benefits/attributes. This interaction is to be expected and indeed has on occasion explained more variance than some main effects (see Kakkar and Lutz 1979 for details). However, the close correspondence between situational factors and product attributes leads to the question: "What are situational factors?" Belk (1974, 1975) proposes that environmental factors should include all variables not included in the description of persons or products. This exclusion rule is debateable, especially given the differences in training of researchers. For example, social norms may be seen as an environmental influence by sociologists, yet modeled as person factors in the prediction of behavioral intentions (Fishbein and Ajzen 1975). However, as long as relevant influences are included, no matter how they are modeled, we should develop a better understanding of consumer behavior.

The response homogeneity between individuals under situational control appears to indicate the absence of the person-situation interaction. This may be an artifact of the research samples (primarily students) which may a priori have been expected to be homogeneous. Other evidence suggests that individuals may be expected to respond differently to the same situation. For example, "Internals" may be expected to be influenced less by environmental circumstances compared "Externals" (Rotter 1966).

In summary, this paper has provided a review of environmental influences on consumer behavior. Situational influences were seen as moderating consumer choice. A contingency model showing the dependency between the specificity of competition (direct to less direct, based on the level of the product hierarchy) and the types of situational influences was proposed. This was used to suggest that usage-situational influences were likely to directly affect non-brand competition. However, if consumer choices were indeed made through multi-stage processes, usage situations may indirectly affect competition at the brand level. A variety of

implications of usage situational influences were discussed including response homogeneity across persons, multiple choice or variety seeking, measures of product substitutability, deterministic choice models, segmentation, and types of situational taxonomies. The validity of each of these implications is researchable. It is hoped that this paper will lead to further exploration of environmental factors in consumer/marketing research.

CONTEXT EFFECTS IN PRODUCT PERCEPTION¹

Michael E. Johnson, The University of Chicago

Abstract

An experiment demonstrates the existence of context effects in consumer perceptions of product similarity. Such effects violate the measurement assumptions of familiar models of product perception such as multidimensional scaling. The observed violations are explained by a theory that represents products as sets of qualitative features.

Introduction

Through years of advertising and use occasions, Budweiser beer has come to be associated with such distinctive features as "Clydesdales", "beechwood aged", and so on. When marketers ask consumers to rate the similarities among beers, their dimensional models of similarity assume that such nondimensional features have no influence. The resulting dimensional representation or "perceptual space" of the brands is assumed to reflect only the differences along uniformly relevant dimensions, such as a beer's "lightness".

The goal of this study is to show that product perceptions are affected by unique features as well as by shared dimensions. Such a demonstration contradicts the measurement assumptions of the familiar models of product perception (multidimensional scaling, multidiscriminant analysis, and conjoint measurement). More specifically, my aim is to show that the salience of different features (and dimensions) will vary with context. Where context can be controlled, such features should influence product comparisons in predictable directions.

After outlining a psychological theory that describes similarity judgments as the result of a feature matching process, the generality of the theory is tested in a consumer products context. The results support such a feature based approach to product perception and attest to the sensitivity of perception to changes in context.

Similarity Judgment as a Feature Matching Process

A dimensionally based technique such as multidimensional scaling (MDS) presumes a full analogy between the cognitive concepts of similarity and dissimilarity on the one hand, and the (Euclidean) geometry of spatial proximity and distance on the other (Cunningham and Shepard 1974). Specifically, MDS postulates that perceived similarity among objects is a monotonically decreasing function of the distances between those objects represented as points in n-dimensional (metric) space. Therefore, such a method is based on both dimensional and metric assumptions.

However, Tversky (1977) has demonstrated that these assumptions may be inappropriate in describing people's perception of similarity. The metric assumptions require that similarity be symmetric. That is, the similarity of a, the subject, to b, the referent, is necessarily identical to the similarity of b to a. The metric models also assume that perceived similarities among objects should be perfectly negatively correlated with the corresponding perceived dissimilarities. In many cases, however, neither of these assumptions holds. For example, Tversky (1977) found subjects' ratings of the similarity of North Korea to Red China to be greater than the similarity of Red China to North Korea. He also showed that when two stimuli in a group appeared to have both more common and more distinctive features than any other pair of stimuli in the group, these two were often judged to be both the most similar and the most dissimilar pair in the group. For instance, the USSR and the United States received both the highest similarity and the highest dissimilarity ratings among the countries judged by Tversky's subjects. Such findings lead one to question the general applicability of both the dimensional and metric assumptions of MDS. Indeed, dimensional interpretations may be inappropriate for a large class of product categories and, if applied, will produce misleading product spaces.

Tversky offers an alternative description of how people make similarity judgments. Judging similarity is a feature matching process.

It seems more appropriate to represent faces, countries, or personalities in terms of many qualitative features than in terms of a few quantitative dimensions. The assessment of similarity between such stimuli, therefore, may be better described as a comparison of features rather than as the computation of metric distance between points (Tversky 1977, p.328).

When faced with a similarity task, people extract and compile from remembered information a limited list of relevant features on the basis of which they perform the required task. As formally stated by Tversky, the similarity between two objects, $s(a,b)$, where a and b are associated with feature sets A and B respectively, is:

$$s(a,b) = \theta f(A \cap B) - \alpha f(A - B) - \beta f(B - A)$$

The similarity between two objects is a function of their common features ($A \cap B$), features of a but not of b ($A - B$), and features of b but not of a ($B - A$). Similarity can be a function of just common or just distinctive features or both depending on the values of the parameters θ , α , and β .

Because format can influence the value of these parameters, Tversky's theory has the power to account for diverse empirical observations. For instance, the North Korea/Red China asymmetry can be explained by a small value of β (in conjunction with Red China's having more distinctive features than North Korea). In other words, when one stimulus is the subject and the other the referent, the distinctive features of the referent do not

¹
The author thanks J. Edward Russo and the Consumer Behavior Laboratory of the Graduate School of Business of the University of Chicago for their assistance in conducting the experiments and preparing the paper. Financial assistance was provided by the Red and White Foundation and the Center for Research in Marketing at the University of Chicago.

receive as much weight in the overall similarity judgment as the distinctive features of the subject. When, in addition, one stimulus has more distinctive features than the other, an asymmetry occurs. Thus, when North Korea is the subject its features map quite well into those of Red China. But when Red China is the subject its features will not map as well into those of North Korea because of the greater number of distinctive features associated with Red China. Similarly, the difference between similarity and dissimilarity judgments can be accounted for by a greater emphasis on common features in the former case (let $\theta >> \alpha = \beta$ in Equation 1) and a greater emphasis on distinctive features in the latter case (let $\alpha = \beta >> \theta$).

The power of the feature model to explain context effects lies in the weights given to the different sets of features. By controlling the context or format within which judgments are elicited, one should be able to strategically manipulate the relative size of these parameters and, as a result, influence product perception.

It should be noted that the empirical violations of MDS that Tversky reported may be explained by other than his feature based set theoretic model. Attempts have been made to reconcile these violations with both metric (Cooper 1979, 1980) and antimetric (Krumhansl 1978) distance functions. The important issues here, however, are the generality of Tversky's findings in a consumer products context and the ability to predict such contextual effects. As long as Tversky's model is a good predictor of contextual effects it will be of obvious usefulness to marketing researchers.

Testing The Theory Using Consumer Products

Method

Experiment 1 tested the asymmetry hypothesis for consumer products. Five product categories were used. Some of these categories were selected because they contain several homogeneous brands with widely varying market shares, such as soft drinks (colas and non-colas) and beers. The others represent product names within a larger, heterogeneous product category where imitation or substitute products must compete with established or prototype products. These products include frozen desserts (frozen yogurt versus ice cream), appliances (toaster versus waffle iron), and fruits (orange versus cangerine).

Assuming that high share or established products are associated with more distinctive features than their counterparts, consumer ratings of similarity in a subject/referent format should be asymmetric. For example, the similarity of Shasta Cola to Coke should be larger than the similarity of Coke to Shasta Cola. Given the nature of these product categories, the predictions that follow are made relative to the specific stimulus pair involved. For example, Coke is the market leader for colas followed by Pepsi and R.C. with brands such as Shasta and Canfield (a brand local to the Chicago area) bringing up the rear. If the features sets associated with the various products roughly correspond to their relative market shares, Tversky's theory predicts that asymmetry should hold, for example, in such cases as R.C. versus Coke and Shasta versus R.C..

Experiment 2 tested the relationship between similarity and dissimilarity judgments among soft drinks (colas and non-colas), beers, and fruits. These categories were chosen because they represent cases where there exist more than one low share or lesser known product and more than one relatively high share or established product.

Assuming that high share products are associated with both more distinctive and more common features, then both the similarity and the dissimilarity ratings among them should be enhanced. This, in turn, should reduce the negative correlation between similarity and dissimilarity. For example, Coke and Pepsi should be both relatively more similar and more dissimilar than other pairs of colas.

Subjects

Participants included students from the University of Wisconsin and residents of the Madison area recruited from ads in the city newspaper and posters on campus. All of the assumptions concerning market shares and associated features were relative to this target market. For example, because Old Style beer is a market leader in this area, it is assumed to be associated with relatively more distinctive features.

Procedure

Stimulus pairs within each product category were randomized and divided into two stimulus sets, (A,B) and (C,D). Subjects were divided into four treatment groups. Treatment group I received subject/referent questions of the form "How similar is A to B?". Group II received questions of the form "How similar is C to D?". Group I was also asked to judge the similarity of pairs of products from stimulus set (C,D) with no subject/referent distinction while group II did likewise for stimulus set (A,B). Group III received questions of the form "How similar is B to A?" and then was asked to rate dissimilarities among stimulus set (C,D). Finally, group IV was given questions of the form "How similar is D to C?" and then was asked to rate dissimilarities among stimulus set (A,E). These four treatment groups were used to avoid having subjects rate subject/referent similarities on the same stimulus pairs they faced in the similarity versus dissimilarity condition.

All of the judgments were elicited in a questionnaire format. Responses were made by placing an X on 125mm rating scales below each question. The scale ranged from "Not At All Similar" to "Very Similar" or from "Not At All Dissimilar" to "Very Dissimilar". After obtaining the judgments, memory probes were obtained on all of the products used in the study. The purpose of the probes was to check on the validity of the assumptions made concerning associated features.

Results

Subject-Referent Asymmetry

The results support the generality of Tversky's criticisms in a subset of the product categories. Significant asymmetry was found to hold for both types of soft drinks and for beers. For example, the similarity of Shasta Lemon Lime Soda to Seven Up was significantly greater than the similarity of Seven Up to Shasta ($t=2.15, P<.05$). Both Pepsi and R.C. were found to be more similar to Coke than vice versa ($t=1.42$ and $t=1.40$ respectively, $P<.10$). Meanwhile, Shasta Cola was more similar to both R.C. and Pepsi than R.C. and Pepsi were to Shasta ($t=2.22$ and $t=1.72$ respectively, $P<.05$). A sample result for beers finds both Huber and Leinenkugel (two local Wisconsin beers) being more similar to Old Style than vice versa ($t=1.95, P<.05$, and $t=1.55, P<.10$, respectively).

A summary of the results for experiment 1 is presented in Table 1. Column 2 presents the average t value of stimulus pairs for which asymmetry was predicted in each

product category. Columns 3, 4, 5, and 6 present the number of stimulus pairs involved, the standard deviation on the t's, a summary t value for each product category, and the significance of each summary value respectively.

TABLE 1
Average Asymmetry Within Product Categories

Product Category	Mean t	n	S.D.	t	significance
Colas	1.39	8	0.54	7.23	sig. α = .005
Non-Colas	1.46	7	0.58	6.64	sig. α = .005
Beers	0.72	8	0.90	2.27	sig. α = .05
Fruit	0.09	8	0.93	0.28	not sig.
Appliances	-0.74	3	0.84	-1.53	not sig.
Desserts	0.97	3	1.25	1.34	not sig.

Similarity versus Dissimilarity

The results of experiment 2 are remarkably consistent with the results of experiment 1. In those cases where asymmetry was significant, a relatively poor relationship was shown to hold between judgments of similarity and judgments of dissimilarity. Likewise, where subject/referent judgments were symmetric, strong negative relationships existed between similarities and dissimilarities. Table 2 presents the least squared regression results which compare the similarity judgments to the dissimilarity judgments for each of the product categories. Columns 2, 3, 4, and 5 present the regression constants, beta coefficients, r2 statistic, and r2 adjusted for the number of independent variables, respectively.

TABLE 2
Similarity vs Dissimilarity Regression Results

Product Category	α	β	r^2	r_a^2
Colas	110.13	-.46	.179	.076
Non-Colas	135.57	-1.15	.585	.499
Beers	131.46	-1.13	.626	.579
Fruit	127.79	-1.06	.849	.830

The cola and beer categories provide the most interesting results. The adjusted r2 for colas is a dismal .076. This small value is due for the most part to the fact that, as predicted, Pepsi and coke were relatively more similar and more dissimilar than any other pairs of colas (see Figure 1). Non-colas do moderately well, obtaining a fit of .585 (see Figure 2). The market leaders in beer, Old Style and Budweiser, were also relatively more similar and more dissimilar than other pairs of beers (see figure 3). The best fit of all occurs for fruits (see Figure 4). Such results are consistent with those in experiment 1 where fruits failed to demonstrate asymmetry.

A preliminary analysis of the thought listings supports the assumptions made concerning associated features. A detailed analysis of the nature of the associations is, however, pending.

Summary and Conclusions

The results of this study support the generality of Tversky's theory in a consumer products context. Contrary to the dimensional assumptions of existing market segmentation techniques, context has a significant and predictable influence on judgments of similarity among products within certain product categories.

Judgments of similarity were found to be poorly related to judgments of dissimilarity for certain products. For example, Coke and Pepsi were found to be both more similar and more dissimilar than other pairs of colas. Therefore, if one builds a product space for colas using similarity judgments, Coke and Pepsi will wind up being very close in proximity. But if one uses dissimilarity judgments as inputs to the construction of such a space, Coke and Pepsi will be relatively distant. Obviously this will have important implications with respect to the interpretation of the market and its use in the development of marketing strategies.

Whether a product is used as a subject or referent in a comparison may also influence the degree of similarity among certain products. If a product is associated with more distinctive features than other products in the same market, such features will detract more from judgments of similarity when that product is the subject rather than the referent in the comparisons. For example, because Coca-Cola is associated with so many distinctive features, a low share cola attempting to position itself close to Coke must be careful not to use Coke as a subject in any direct comparisons of the two products.

The consistency of the results in experiment 1 with those in experiment 2 provide convergent validity for the results as a whole and for Tversky's theory. In many cases it is simply more appropriate to view a product as being associated with sets of features than as varying on a small number of shared dimensions. As to why the homogeneous product categories were the only ones prone to such effects is the subject of the author's current research.

A MEANS-END MODEL FOR FACILITATING
ANALYSES OF PRODUCT MARKETS BASED ON CONSUMER JUDGEMENT

Jonathan Gutman, University of Southern California

Abstract

Day, Shocker, and Srivastava (1979) have discussed a number of customer-oriented approaches for identifying product markets. This paper presents a means-end chain model for facilitating analyses of product markets using consumer judgements. The model is based on categorization processes which consumers use to create sets of substitutable products.

Introduction

Day, Shocker, and Srivastava (1979) have discussed a number of customer-oriented approaches for identifying product markets. The approaches include decision sequence analysis, perceptual mapping, and several variations for obtaining direct consumer judgements of substitutability (free response data, direct grouping into categories, products by uses analysis, and substitution-in-use analysis).

Although these approaches differ, they share a number of related aspects. These aspects can all be embodied in a model of consumer categorization processes that relates "ends" in terms of consumer values to "means," which often are the products consumers consume. Such a model can provide a basis for increasing our understanding of how consumers cognitively define competitive sets of products.

This paper will briefly outline and point out the critical aspect each of these approaches. Then the model will be presented. Lastly, some examples of relevant research will be presented that suggest how the model facilitates research on product markets.

Approaches for Obtaining Consumer
Judgement of Substitutability

Decision Sequence Analysis

Bettman (1971) and Haines (1974) have discussed the use of protocols of consumer decision making which indicate the sequence in which various criteria are employed in reaching a final choice. The data are typically gathered by asking shoppers to verbalize their train of thought as they make actual shopping decisions. The critical aspect of this approach is the specification of attributes used in the choice process and the sequence in which they come into play.

Perceptual Mapping

Perceptual maps are created by a variety of techniques that create geometric representations of consumer's perceptions of product markets. Such maps require that the relevant product market be already defined before the start of the study. However, it is possible to create maps for "different levels of product competition to explore competitive relations at the level of product types, variants, or brands" (Day, Shocker, and Srivastava 1979 p.14).

Consumer Judgements of Substitutability

The Free Response approach (Green, Wind, and Jain 1973) allows the respondent to decide how similar brands must be

before they can be considered as substitutes. Consumers are presented with target brands and asked to free associate the names of similar or substitute brands. Frequency and order of mention are used as indications of similarity.

Direct grouping into categories (see Gutman 1979, Gutman & Reynolds 1979, and Bourgeois, Haines, and Sommers 1979) involves asking consumers to directly assign products to categories based on their judgments as to their degree of substitutability. Products-by-uses analysis (Stefflre 1979, Myers & Tauber 1977) involves ascertaining which usage situations are similar by virtue of their evoking the same benefits. Competitive products are determined by their being appropriate in equivalent usage situations. Substitutability-in-use analysis (Srivastava, Shocker, and Day 1977) is a refinement of the above approach brought about by a three-stage approach to refine the set of usage situations to be used.

Each of the above approaches requires that we know something different about consumers' cognitive structure. Decision sequence analysis requires that we understand the hierarchical ordering of elements in consumers' cognitive structure. The use of perceptual mapping requires that we be capable of representing the levels of inclusiveness at which products may be represented within a consumer's cognitive structure. The free-response approach emphasizes the individual nature of consumers' categorical systems. The direct grouping approaches emphasize the need to understand equivalence ranges (when are products substitutable or how similar do they have to be to be substitutable). And the products-by-uses analysis suggests that all of the above aspects vary by circumstance or situation.

Development of a Means-End Chain Model

It is possible to develop a model of consumers' cognitive structure that will provide for representation of all of these aspects. Such a model offers a theoretical and conceptual structure for connecting consumers' values to their behavior (Rokeach 1968, Howard 1977, Vinson, Scott, and Lamont 1977). Models of this type can be subsumed under the rubric of means-end chains. Means are objects (viz., products) or activities that people engage in (viz., running, reading, etc.). Ends are valued states of being, such as happiness, security, accomplishment. A means-end chain is defined as consisting of an interconnected set of cognitive elements that allows a person to select objects or activities that enable him to achieve his desired end states.

Thus, the means-end chain permits us to focus on the basic aims consumers have in life while not losing sight of how these aims influence choices in specific situations. The process of categorization is proposed as the mechanism by which consumers organize thinking about specific product alternatives so as to create arrays of products which will be instrumental in helping them achieve their values. If this connection can be made, the bases consumers have for creating sets of substitutable products will be understood more thoroughly.

Categorization processes, then, represent ways people segment their environments into meaningful groups by creating equivalences among nonidentical stimuli. Thus, for example, the categories of paper towels, toothpaste,

or coffee have meaning to people because the objects in these categories all have something in common.

This process of categorization takes place at many levels of inclusiveness, which refers to the degree of similarity among products in a category. Brands of paper towels grouped together would represent a category of low inclusiveness. If consumers distinguish between plain paper towels and those with a pattern, two product categories of lower inclusiveness would be created. If paper towels were grouped with paper napkins, cups, and tissues, a more inclusive category of "paper products" would be created.

Categorization as a Basis for Means-End Chain

Groups or categories of products (product classes, for example) have to be related systematically to the higher-level ends if the "chain" is to serve its instrumental purpose of enabling the person to achieve his or her values. This means that values have to be translated from their context at the more inclusive levels of the chain to the less inclusive levels where products are categorized into product classes, thus establishing sets of products which will be competitive (alternative satisfiers of the same ends).

The basis of this clustering is mutually determined by the object properties and value-determined criteria for goal instrumentality. This categorization process takes place at each level of the means-end chain as categories of greater inclusiveness are formed at higher and higher-levels of the means-end chain. For example, some consumers may treat the entire category of soft drinks as a single category of sugary substances that ought not to be consumed, while others regard them as tasty and delicious. Others may make a distinction between fruit drinks and carbonated drinks. Still others may make a distinction between drinks that are "fun to drink" (soft drinks) and those that are "good for you." Most consumers will be in agreement as to the identity of products--what is a soft drink and what isn't. Differences in consumer categorization are less at low levels of inclusiveness (where assignment to categories is based on product attributes) than at high levels of inclusiveness (where categories are based on function or value instrumentality). Consumers group products in different categories, depending on which features they emphasize and which features they ignore.

These categories are created by the application of a cognitive mechanism called a "distinction." Distinctions are dichotomies that represent the end points of dimensions along which products may be compared. If two products can be compared using a hot/cold distinction, this indicates that they may be compared by temperature, although they may differ with respect to temperature. An array of products can be created by applying this distinction to any of a limitless number of products. However, many products may not be comparable on this distinction. If a consumer doesn't think of a chain saw, a dry cleaner, or a box of paperclips as being either hot or cold, then none of these objects would be part of the array. Other products, such as orange juice, coffee, tea, milk, water, corn flakes, oatmeal, etc., could be compared on this basis.

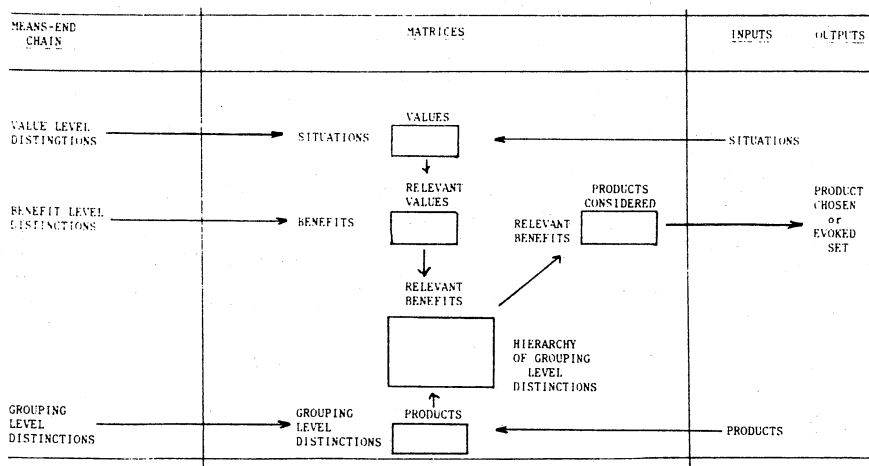

The resulting array can contain as many categories as products or just one category (if all products were thought to be the same temperature). The essential point is that the distinction being dichotomous has nothing to do with the nature of the array of products created by its application. A distinction is not an array of products--it is a dichotomous cognitive element in which the two parts of the dichotomy have some meaningful relation to one another. What is meaningful is a personal decision for each consumer to make.

Description of Means-End Chain Model

Two major events occur in the development of a means-end chain. One is the crystallization of values to the point where they become capable of articulation into goals or valued states. This event occurs at the top of the chain. At the bottom of the chain, individual products have to be arrayed into product classes to limit the complexity of the choice situation to acceptable levels. Products have to be given meaning in terms of the internal coding system established by the individual for making sense of the world (Olson and Muderrisoglu 1978).

These two issues define the basis for the model shown in Figure 1. The figure is divided into three parts: the means-ends chain, matrices, and inputs and outputs. The figure shows that the means-end chain is comprised of three levels of distinctions--values, benefits, and grouping. The focus of distinctions at the values and benefits

FIGURE 1
Means-End Chain Model

levels is on what products can do for the consumer. Distinctions at the grouping level focus on properties of the product or evaluations of properties of products. Inputs to the system are products and situations; outputs are products chosen for final consideration. Matrices are intersections between inputs and means-end chain distinctions or between outputs from such matrices.

Situations encountered by consumers are assessed in terms of values to be sought in each. This occurs in the situations-by-values matrix and results in a set of relevant values emerging that will guide behavior in a given situation. These relevant values are arrayed in a matrix with potential benefits. Analysis of the instrumentality of the benefits for achieving relevant values results in a set of relevant benefits which guide the choice of product alternatives.

At the bottom of the figure, grouping level distinctions form a hierarchy wherein the identity and evaluation of product alternatives are determined at different levels of inclusiveness.

At the lowest levels of inclusiveness, products are grouped together in accordance with Howard's notion of semantic structure or Lunn's (1972) organization of ways of satisfying consumer needs by product types, product variants, and brands. Product types satisfy different needs beyond generic needs (tooth paste vs. tooth power; hot vs. cold cereal). Product variants are variations within types (with or without fluoride, presweetened vs. unsweetened). And brands represent minor differences within variants. Thus, brands as specific alternatives are at the bottom of the hierarchy; those are subsumed by product variants, and product variants are grouped by product type.

At the upper levels of the hierarchy, evaluative categories subsume identity categories. Thus, for cereal, nutritious vs. unnutritious or tastes good vs. doesn't taste good might subsume distinctions based more on physical properties of cereals. The distinctions at the top of the grouping hierarchy are implied by, or predicted from, the distinctions at the bottom of the hierarchy. Relevant benefit distinctions for the situation are applied to the hierarchy of grouping distinctions. This determines the level in the hierarchy at which a set of products would be selected for further processing--perhaps the level at which the relevant product market would be defined for that consumer. Products at this level of grouping would themselves be compared in the "relevant benefit distinctions by products" matrix. This comparison would result in a product to be chosen for that situation or a set of products from which a choice would have to be made on a nonvalues-related basis.

Values, Situations, and Value-Situation Matrices

Consumers obviously encounter many potential product-use situations. There are many ways of defining and describing such situational variables (Belk 1975). But for the level of analysis referred to in this context we will follow Fennell (1978), who defines a situational unit as corresponding "to the activities and conditions for which products are created and marketed, such as doing the laundry, feeding the dog, having a headache."

Consumers have valued ends they are trying to achieve. And consumption situations provide them with an opportunity to achieve these values. Each consumer learns over time which choices in a given situation are instrumental to achieving values and which are not. Thus, consumers learn to perceive certain situations as opportunities for achieving certain of their values.

The situations by values matrix is a means by which the accumulated experience of the consumer can be represented. It illustrates the process by which a particular set of values comes to guide the selection of benefits sought in a given consumption situation. All of a consumer's values can't be achieved in one situation, and, frequently, achieving some values means not achieving other values. This point of view is consistent with the conclusion that situational influence is a pervasive factor in consumer behavior (Belk 1975, p. 161).

Grouping-Level Distinctions

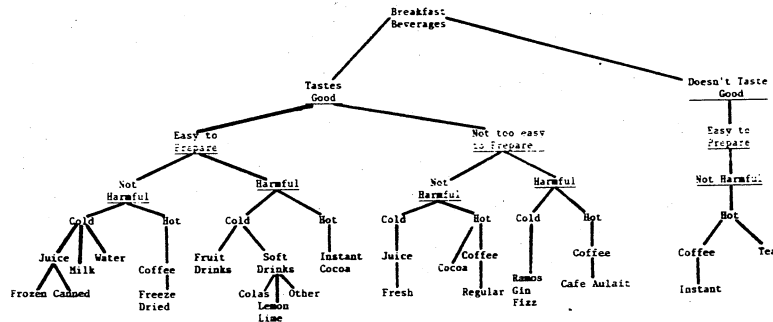

The grouping level is the level at which meaning is ascribed to products by grouping them together with other similar products and giving them a group label. Physical and surface properties of products are the bases for grouping products at the grouping level. As the most immediately perceived aspects of products, they serve to identify them in their most fundamental sense. Cars are to drive; refrigerators refrigerate; stoves cook; peas, green beans, carrots, etc., are all vegetables. It is possible to discriminate products more finely within each of these categories. There are many kinds of vegetables (root crops, green leafy, squash, etc.), many ways of classifying cars, and many types of refrigerators.

Finer and finer discriminations within categories and broader and broader discriminations of subsuming categories (cars are a means of locomotion; vegetables are food; refrigerators are appliances) create product hierarchies. The number of levels in the hierarchy is a function of the knowledge of the consumer and his or her interest in maintaining a cognitive structure of varying amounts of complexity. Someone who doesn't like coffee would have a much flatter hierarchy of types of coffee than a coffee connoisseur would. Obviously, then, product markets would be defined differently for different types of consumers.

Distinctions at this level often have the form of logical negation, which means that one side of the dichotomy is "not" (" \sim " in Boolean algebra) what the other side "is." Soft drink vs. not a soft drink in effect creates one group of products--the other "group" representing all other objects not in the first group (e.g., fruit juice, water, elephants, etc.). Obviously, such a distinction could be applied to all objects, whereas "hot vs. cold" implies that objects be comparable along a temperature dimension. Distinctions in the form of logical negation create the simple identity groupings that are characteristic of the lower levels of the grouping hierarchy.

At low levels in the grouping hierarchy, distinctions serve to identify products; at higher levels within the grouping hierarchy, evaluative distinctions subsume those identity distinctions. At the lower levels, where identity is the focus, level of inclusiveness accounts for the level of a distinction within the hierarchy. Thus, in Figure 2, which shows one person's grouping hierarchy for breakfast beverages, soft drink subsumes colas, lemon-lime, and other flavors. At higher levels in the grouping hierarchy, the level of a distinction is determined by its ability to separate products into preferred and nonpreferred sets (see Tversky's (1972) theory of sequential choice). If "not easy to prepare" meant a product was not acceptable for use regardless of any other properties, it would be more functional to have it subsume "good for you"--"not good for you." However, if a consumer would be more likely not to consider a product if it were "not good for you," even if it were easier to prepare than "good for you," "not good for you" would be at a higher level in the hierarchy. The goal of categorizing products at the grouping level is to identify products and array them into

FIGURE 2
Grouping Hierarchy for Breakfast Beverages

sets based on their possession of attributes that imply the ability to provide desired benefits for the consumer.

Discussion

The model presented above includes all the relevant aspects of the measures of consumer judgement that are used to measure product markets. It allows for the situational selection of relevant values that in turn select appropriate benefits to be sought in the consumption situation. Benefits, in turn, determine the level in the hierarchical structure at which products will be aggregated for further consideration. Thus, there are families of product markets at different levels of inclusiveness, each level of which is appropriate in different sets of circumstances. The criterion of substitutability of alternatives for defining product markets is consistent with the notion that values guide behavior and determine relevant objects for consideration in those situations.

The model also suggests that categorizing products at the values level leads to the development of a wider, more complete definition of relevant product markets than starting with the products themselves and trying to establish categories. Several studies the author has done bear on these issues. The first study (Gutman, 1978) involved eliciting distinctions from respondents and having them sort products into categories based on these distinctions. Twenty triads (sets of three cereals in this instance) were presented to each respondent, who was asked to indicate a way in which all three products could be compared. Then the respondent was to specify how two products are the same and different from the third. This allowed us to define the two poles or ends of the dimension defined by the distinction being made. Respondents were then asked to sort 23 brands of cereal into categories on the basis of their distinctions. They could use as many or few categories as desired.

Another group of respondents was asked to sort the cereals into categories without having been asked to elicit any distinctions they might have. After sorting the cereals, these respondents were asked to label the categories they had created.

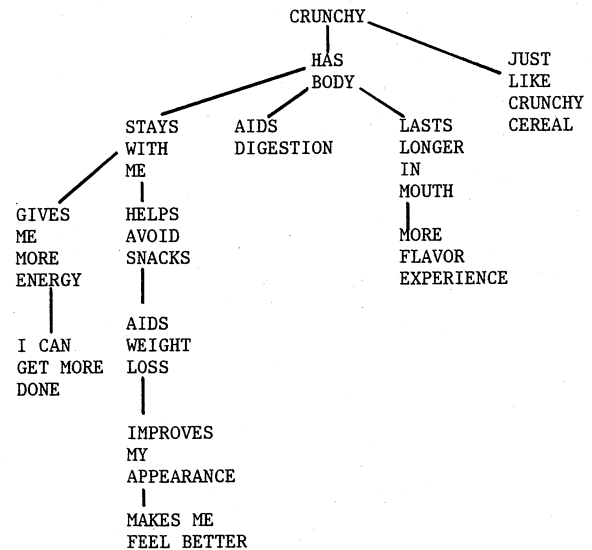

The results indicated that it is difficult to get many distinctions from people. People don't have too many ways of thinking about products (at least for breakfast cereals which may not be too complex). The free sortings were different from the sortings based on the distinctions in that the former yielded sets of nominal categories rather than dimensional arrays. People tended to see products as

organized wholes and didn't look for ways to link dissimilar products to each other.

This might suggest narrow product markets definitions where only highly similar products are considered as substitutes. If consumers are concrete and incapable of thinking abstractly about products, different types of products are not likely to be seen or thought of as alternatives.

It is possible to get consumers to operate at higher levels of inclusiveness, but they have to be "encouraged" to do so. Respondents can be asked to state their preferred poles for each distinction they elicit. Then they are asked why they prefer that pole (or that end of the dimension). The answer to the "why" question becomes the basis for asking another "why" question, and so on until the respondent can answer no further "why" questions. The results of such a procedure (referred to as laddering--see Bannister, (1970) are shown in Figure 3. The figure can

FIGURE 3
Higher Order Implication Chain
Extending from "Crunchy"

be interpreted as providing a chain of implication between the distinctions at various levels in the hierarchy from means to ends.

Another study (Gutman and Reynolds 1979) focused on getting respondents to categorize products (drinks in this instance) at higher levels of inclusiveness. Here again, laddering was used to get distinctions at higher and higher levels of inclusiveness. A content analysis of distinctions at each level showed initial distinctions referred to the contents of the drinks or related to their immediately observable properties. Distinctions at higher levels referred to functions (what the drinks did to/for the person) or end states of being achieved through consumption of the drinks. An example of one respondent's hierarchy of responses to the laddering process is shown in Table 1.

TABLE 1

Example of Laddering Derived from Repertory Grid Procedure Using the Triad: Soft Drink, Fruit Drink, Fruit Juice

Level	Distinction
1	Fresh vs Processed
2	More Vitamins vs Less Vitamins
3	Lower Sugar vs Higher Sugar
4	Low Calories vs High Calories
5	Good for Weight Control vs Not Good for Weight Control
6	Smaller Size Clothes vs Larger Size Clothes
7	Husband at Home vs Husband Out

The sorting data consisting of a "persons-by-drinks" matrix, with category membership nominally coded within, served as the basis for generating the distance data for input to POLYCON, a multidimensional scaling program (see Rosenberg and Kim, 1975 for the procedure used). Three maps are shown in Figure 4. They show the product space in two dimensions for sorts based on distinctions at the first, third, and fifth levels (as obtained through the laddering procedure). The changes in groupings of drinks can be readily seen. The juices, fruit drinks, and soft drinks show movement across levels. In effect, these figures represent cognitive maps of product markets at different levels of inclusiveness. One has to get the consumer to consider the benefits derived and values satisfied to develop the proper context for arraying products into meaningful groups. Otherwise, the analogy is similar to that of the problem with SIC codes in that grouping is based on properties other than those related to consumption.

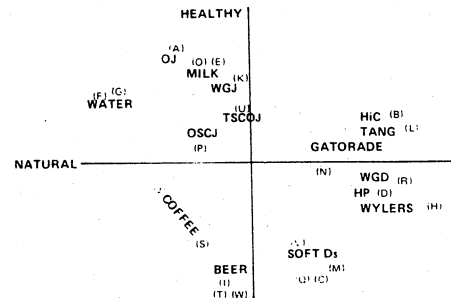

The last study (Gutman 1980) shows some evidence of preferred ranges for equivalence in sorting products into categories. Consumers differ in terms of the limits of what they consider similar. Some people will accept a slight basis of comparability as enough to group two products together. Other people would only do so if the two products were highly similar. This tendency may be related to actual product market limits as well as to cognitive mappings of such product markets. If people are narrow and concrete in terms of what they consider equivalent, then their cognitive view of the world will restrict their breadth of their solutions in terms of searching for means to satisfy their ends.

| (L) Tang | |

Conclusion

The paper has presented a means-end chain model for facilitating the analysis of product markets based on consumer judgement. The levels represented in the model-extending from values to benefits to product attributes-provide for an integrated set of product groupings at different levels of inclusiveness. This family of product groupings should permit managers to relate levels of market aggregation to the criteria used by consumers at those levels. Furthermore, operating at the values level can provide the most comprehensive view of the market in terms of learning about competition from outside traditional market boundaries.

The model has the advantage of letting the consumer decide the criteria to be used in grouping products. It may exhibit the linkages between physical aspects of products (which may offer a misleading view of product markets from a consumer perspective), benefits provided by these products, and values consumers are striving for in their consumption of these products.

Laura S. Sims, The Pennsylvania State University

Abstract

Three characteristics of cognitive structure, considered to be the coded representations of information in memory, are identified and defined--dimensionality, abstraction, and articulation. Two measurement procedures, free elicitation and the repertory grid, were hypothesized to provide indicators of these three constructs. Reasonable levels of convergent and discriminant validity were obtained for the proposed construct measures in a study of consumers' cognitive structures regarding nutrition. Suggestions are offered for further research which can more firmly establish the construct validity of these characteristics of cognitive structure.

Introduction

Although much has been written about consumers' cognitive structures for brands and product categories, little direct research has been undertaken. Related work has focused on attitudes, where the major interest concerns belief structures and their relationships to attitude (e.g., Lutz 1975, Olson and Dover 1978). Although some researchers have been concerned with consumers' stored information about brands or products (cf. Woodruff 1972), few have tried to measure memory structures directly. Research by Bettman (cf. 1979), Olson and Mudderisoglu (1979), and Russo and Johnson (1980) are among the few exceptions.

Clearly, however, cognitive structure issues are involved in many research topics (Olson 1978b), although this has not always been explicitly recognized. For instance, information acquisition (cf. Jacoby, Szybillo and Busato-Schach 1977) is essentially concerned with the formation of cognitive structures. Attempts to measure various effects of product familiarity (e.g., Park 1976, Raju and Reilly 1980) can be seen from a cognitive structure perspective (Marks and Olson 1981). Advertising effects research (e.g., Wright 1973) can be interpreted as examining the interaction between advertising and cognitive structure (Calder 1978, Mitchell 1980, Olson 1980, Olson and Dover 1978). Indeed, the increasing interest in the cognitive processes involved in consumers' processing of information, especially as they are influenced by organized structures of knowledge stored in memory, forces us to realize that much (if not all) of consumer research involves the concept of cognitive structures (Bettman 1979, Olson 1978b).

Thus, it seems likely that the concept of cognitive structure--as it refers to the encoded representations of information in memory--will become a central concept in models of consumer behavior. This importance reflects the trend in cognitive psychology where it is now widely recognized that one's acquired knowledge about specific domains has very powerful effects on a variety of cognitive processes and outcomes (see Lachman, Lachman and Butterfield 1979). Many cognitive theorists are actively considering the

content and organization of the knowledge held in cognitive structure and its effects (e.g., Anderson 1976, Kintsch 1974, Anderson, Spiro and Montague 1977, Tulving and Donaldson 1972, Shank and Abelson 1977, among many others). A variety of concepts such as schemas (Norman and Bobrow 1975, Norman 1979), scripts (Shank and Abelson 1977), frames (Minsky 1975), and hierarchical semantic memory structures (Collins and Quillian 1969), to name only a few, have been proposed as models of or metaphors for cognitive structure.

Interestingly, the published literature contains many conceptualizations of cognitive structure, but relatively few attempts at operationalization. Many researchers are theorizing about the form and effects of cognitive structures, but few have tried to measure them directly (see Puff 1979). As one example, the cognitive structure concept of memory schemata or schemas has become popular in social psychology (Taylor and Crocker 1980). Yet to our knowledge, no one has attempted to measure the content and organizational structure of a schema directly, although the research of Markus (1977) comes close. Typically, researchers have been content to predict certain behaviors (e.g., reaction time to questions) that should occur if a certain type of schema is indeed present, and then create an experimental setting to demonstrate that effect (cf. Tesser 1978). The schema itself--i.e., content and internal organization--is usually not measured directly, or even relatively directly.

Moreover, there has been little effort directed toward developing hypothetical constructs which describe broad, generalizable characteristics of cognitive structures. Except for Scott's (1963, 1969, 1974) work dealing directly with cognitive structure, most researchers have theorized at a very abstract level about the ways in which knowledge representations may be coded and/or organized in memory. Few have been concerned with developing constructs at an intermediate level of abstraction that define the specific characteristics of cognitive structure that should influence other cognitive processes, and ultimately, overt behavior. This intermediate level is a necessary compromise in order to move away from the highly abstract theoretical level to a more operational level, yet avoid the idiosyncratic level of measuring the unique contents of each person's schemas.

The present research can best be understood against this background of developing interest in cognitive structures. We have three objectives for this paper: (a) to present our initial conceptualizations of three major characteristics of cognitive structure, (b) to briefly describe the empirical indicators we have developed to measure each characteristic, and (c) to present results from an initial study intended to establish the convergent and divergent validity of these indicators. The long-term goals for our research program, the first construct validity study of which is detailed here, are to develop a clearly conceptualized model of cognitive structure and a set of reliable and valid indicators of the major components of that model. Once reliable and valid measures are identified, we hope to learn more about how differences in cognitive structures influence a variety of interesting information processing behaviors such as product evaluations, purchase decision-making, responses to advertising, and information search, to name but a few.

Basic Assumptions

Before presenting specific details, it is first necessary to

¹This research was supported by the Science and Education Administration of the U.S. Department of Agriculture under Grant No. 5901-0410-8-0151-0 from the Competitive Grants Office to the second and third authors. The data collection assistance of Elizabeth Leung and Roslyn Weinstock is much appreciated.

describe several basic assumptions that provide the theoretical foundations for this research. Essentially, these are metatheoretical ideas, so abstract that they can not be easily subjected to empirical verification. Still, it is valuable to identify the conceptual framework which led to this work so that the reader can trace the logic underlying our approach.

Perhaps the most basic assumption is that people, through various encoding processes, cognitively represent information from the external world in symbolic form. We term these coded representations "knowledge," after Russo (1978). Our use of the term is broad; knowledge can refer to semantic, belief-like representations as well as affective and emotional, perhaps even visual, representations. Another basic assumption is that these coded representations are stored in memory in an organized or structured manner. A useful metaphor for conceptualizing such a cognitive structure is a network of interrelated, associated concepts. The links between concepts might be based on the meaningfulness of the association or the semantic relatedness between the concepts (see Collins and Loftus 1975). A third important idea is that a concept or group of concepts can be activated or "retrieved" from memory merely by attention to external or internally generated cues (Collins and Loftus 1975). In summary, then, information is presumed to be encoded and stored in organized networks of representations that we can call structures of knowledge, or cognitive structures (cf. Hayes-Roth 1977). Such structures presumably can be activated from memory, either in part or perhaps as a "unit," and used in various cognitive processes (e.g., Olson 1978a).

Dimensions of Cognitive Structure

What are the major characteristics of the network of knowledge that constitutes a cognitive structure? The cognitive psychology literature provides little help in answering this question. Instead, we turned to the cognitive style literature (see Goldstein and Blackman 1979 for review), and especially to the work of William Scott (1963, 1969, 1974), a social psychologist. During the early 1960's there was substantial interest in "cognitive structure" concepts such as cognitive complexity. Much of this work was "stylistically" oriented in that it attempted to describe and measure regular patterns or styles of behavior. For the most part, little attention was paid to the cognitive representations in memory that, with the hindsight provided by our information processing perspective, we now see as responsible for the observed behavior.

We have modified selected concepts from this earlier work in adapting them to our cognitive structure perspective. Actually, this process was less procrustean than it may appear. Scott's work in particular was fairly easy to translate into a memory structure orientation. Essentially, we selected major behavior patterns that previous researchers felt to be important, and we attempted to define the characteristics of a cognitive structure that could or should produce such behavior. Then, we developed conceptual definitions for each major characteristic of cognitive structure. In our scheme, then, the observed behaviors which previously had been the major focus of interest are now treated as outcomes of the cognitive structure constructs, and therefore, as potential indicators of these characteristics. We recognize, of course, that the constructs and measures of this initial nomological framework are likely to undergo substantial changes during the course of the next few years' research. They are offered here as a potential stimulus to that research effort, not as the final product.

Dimensionality

The notion of cognitive complexity provides the clearest example of our approach. Goldstein and Blackman (1979,

p. 115) state that "The cognitively complex individual is one who differentiates among concepts and is able to make discriminations on each of these conceptual dimensions." Note that this definition is strictly operational. It specifies two behaviors to be observed, based on which one can label an individual as more or less cognitively complex. Following Scott's (1969) lead, we conceptualized two aspects of cognitive structure that might be expected to produce these behaviors. One is dimensionality, defined as the number of salient, activatable (see, Olson, Kanwar and Muderrisoglu 1979) concepts stored in memory. Here we are concerned with the number of activatable concepts associated with a particular content domain.

Articulation

The second cognitive structure characteristic is articulation, defined as the number of category representations or levels for each salient dimension in memory. People who possess larger numbers of activatable concepts for a domain have a cognitive structure that is higher in dimensionality. Presumably, they are capable of using more concepts to perform evaluation or choice tasks regarding that domain, although whether or not they do so may be influenced by other factors. Likewise, people who are higher in articulation should, in general, be able to make finer distinctions between stimuli in terms of that dimension than those whose cognitive structure dimensions are less articulated. Thus, people high in both dimensionality and articulation should evidence "cognitively complex behavior" in certain tasks, because of these characteristics of their cognitive structures.

Abstraction

Abstraction is the third construct of interest in this paper.² As a characteristic of cognitive structure, abstraction concerns the degree of abstractness of the salient, activatable dimensions stored in the structure. A cognitive structure's abstractness is necessarily a relative concept, based on the mix of more and less abstract and concrete representations in the structure. This concept seems highly related to ideas such as hierarchical groupings of concepts (Collins and Quillian 1969), chunking (Simon 1974), unitization (Hayes-Roth 1977), and categorization (Rosch 1975). Abstraction can also be considered as a recoding process in which a new code is assigned to represent several other usually less abstract or more concrete codes. The abstraction process is functional since recoding reduces the number of salient concepts in a structure. Because larger amounts of knowledge are now represented by a smaller number of more abstract dimensions, using more abstract cognitive structures should require less of a person's limited cognitive capacity compared to using less abstract, more concrete structures.

These three characteristics--dimensionality, articulation, and abstraction--are proposed as critical features of cognitive structure. These (and perhaps other) features of someone's stored knowledge are expected to affect how that person processes information relevant to that domain. Of course, it is relatively easy to propose constructs. Compelling evidence for the validity of these constructs requires independent measures of the characteristics, in addition to accurate predictions of their presumed effects. Measures of the three characteristics are discussed below.

Measurement Approaches

The three cognitive structure constructs are defined conceptually in terms of the coded representations organized

²We have proposed two additional characteristics of cognitive structure--interrelatedness and centrality--but these are not discussed here.

in network-like memory structures. Therefore, measures of constructs must tap into memory, at least relatively directly. Most of the procedures used in past research to measure cognitive complexity are inappropriate for this purpose. For instance personality-like measures such as the scale used by Kasulius and Zaltman (1977) provide no indication of the content or organization of cognitive structure. Instead, we developed two procedures to indicate the proposed characteristics of cognitive structure more directly--free elicitation and a modified repertory grid task.

Free Elicitation. Free elicitation is the "newer" procedure, having been used relatively little in cognitive research. The conceptual basis for free elicitation is activation theory (Collins and Loftus 1975). The basic idea is that exposure to a cue activates the cognitive representation of that stimulus. Then, that activation spreads to other related concepts via the associations or linkages between representations. Thus, an entire structure (if one exists) might be activated in a relatively short time. Once a structure is activated and available for processing, the subject should be able to verbally report some, perhaps much of the structure content. By this logic, then, the elicited responses may be considered to reflect the characteristics of the cognitive structure.

The present research concerned peoples' nutrition knowledge structures. For each subject, we used four different probe cues to initiate the elicitation. In fact, we used a multiple elicitation procedure in which each elicited concept was itself subsequently used as a probe to stimulate additional elicitation. In the present study we used three or four "layers" of probes which produced a large number of idiosyncratic responses for each subject.³ Based on Epstein's (1979) arguments, we combined all the elicitation for the four probes to produce indices of dimensionality and abstraction. The total number of unique (multiple mentions of a concept were counted only once) nutritional concepts that are elicited were considered an indicator of the dimensionality of nutrition knowledge. And, the number of those nutrition responses that were relatively abstract and concrete were considered indicators of the abstractness and concreteness of a person's nutrition cognitive structure.

Repertory Grid. The repertory grid is a more structured elicitation procedure than the free elicitation technique. The repertory grid was originally developed by Kelley (1955) to identify the constructs people use to structure their perceptions of the social world. In adapting the repertory grid techniques to our purposes, we modified the original procedures somewhat.

Basically, our repertory grid methodology begins by presenting subjects with several sets of food concepts, three at a time. We use types of food as stimuli since we are

interested in nutrition knowledge structures. For each triad, subjects are to state all the "ways" in which any two of the foods are similar and different from the third. When no new concepts can be elicited, another triad is presented, and so on. We have found that after 10 to 15 triads most subjects produce few new concepts. The next step is to select the specific concepts of interest--here, nutrition concepts. For each unique nutrition concept elicited, subjects are asked to sort 20 or 30 types of food (each food printed on a card) into "piles," so that the foods in each pile are similar with respect to that particular dimension. Subjects are free to use as many or as few groupings as they wish. After the free sort, subjects are asked to name each group (pile) and describe why those foods were clustered together on that nutrition dimension.

The data produced by the modified repertory grid procedure provides possible indicators of all three knowledge structure characteristics. The number of unique nutrition concepts elicited may indicate the dimensionality of the nutrition knowledge structure. The elicited nutrition concepts can be coded in terms of their abstractness/concreteness. And, the average number of categories or levels produced in the sorting tasks may indicate the degree of articulation of the nutrition cognitive structure.

Knowledge Test. The two methods described above were developed to provide relatively direct indicants of stored cognitive structures. It was considered valuable to compare these measures with a more traditional method of measuring knowledge. A common method of measuring consumers' knowledge regarding a domain is to have them complete a paper-and-pencil test consisting of several specific, usually factual questions about the topic (cf. Edell and Mitchell 1978). This is the dominant technique used by nutrition researchers to measure people's nutrition knowledge (see Cosper and Wakefield 1975, Fusillo and Beloian 1977, Grotkowski and Sims 1978).

For the present study, we constructed a 23-item scale containing a variety of factual questions about nutrition. These items were selected from a larger set of questions commonly used in nutrition research and additional items constructed by the authors. First, items identified as ambiguous in small-scale pretests were removed or rewritten. Then the revised scale was given to a group of 250 respondents, 150 college students and 100 adult participants in a continuing education course. Each of the final 23 items had positive item-total correlations (average $r = .23$). A factor analysis produced no clear factors beyond a general factor, and Cronbach's coefficient alpha, an indicator of internal consistency, was .68 for the entire test. Scores on this knowledge "test" were related to the measures of dimensionality, abstractness, and articulation.

Methods

Subjects

The data collection procedures used in this research required substantial experimenter effort (as much as 2-1/2 hours per subject). Therefore, final sample size was restricted to 18 women who had the primary responsibility for food shopping and meal preparations in their households. Because the research purpose was to establish the convergent and divergent validities of the possible indicators of cognitive structure and their interrelationships, any person with cognitive knowledge about nutrition (nearly everyone, probably) was an appropriate subject. Therefore, because sample representativeness was not a major concern, subjects were graduate student wives and secretaries at Penn State University, selected on a convenience basis. All voluntarily agreed to participate by signing an informed consent form and were paid for their participation at the rate of \$4.00 per hour.

³We consider free elicitation to be subtly different from the free recall paradigm commonly used in cognitive and to some extent in consumer psychology (e.g., Johnson and Russo 1978). In free recall, the focus tends to be on a particular learning situation and on the specific episodic memory traces about that event. Thus instructions tend to be like, "Tell me which words (or ads) you remember seeing yesterday." In free elicitation, the researcher usually seeks probe cues that will trigger or activate a particular cognitive structure in semantic memory. Although the content of that structure probably was acquired over many learning occasions, these specific occasions are of little or no interest. It is interesting to note that the free elicitation procedure, as derived from activation theory and associationist network theory, is essentially identical to the method advocated by Fishbein (1967) for identifying salient beliefs.

Procedures

Two stages of data collection are relevant for this paper. At the first stage, 29 subjects went through the free elicitation procedures described earlier. Each subject was run individually. Four initial probe cues were used for each subject. Fifteen subjects received as probes the phrases, "good health, balanced diet, nutritious food, and vitamins," while the other 14 subjects responded to "having good health, obtaining a balanced diet, eating nutritious food, and getting enough vitamins." For present purposes this manipulation is ignored. As described earlier, elicited responses to the four original probe cues were used in turn as probes and so on again, "down" to four levels. Interviewers recorded subjects' responses as they were elicited on special scoring sheets. This multiple probe procedure was intended to maximize the chances of activating parts of each subjects' nutrition knowledge structure(s). It resulted in a substantial number of elicited concepts per subject ($M = 47.1$). Following the elicitation, subjects completed the knowledge questionnaire, plus several other questions. On average, this session required from 1 to 1-1/2 hours.

The repertory grid was conducted at a second session about two months later. Due to some attrition and one refusal, only 18 of the original 29 subjects participated in the second session. The repertory grid procedures were followed as described above. An average of 34.1 concepts were produced for each subject. This session required about one hour.

Results

Our major interest is in the convergent validity of the elicitation and rep grid procedures for measuring dimensionality and abstraction, and in the relationships (a) between these two constructs and articulation and (b) between all three concepts and the scores on the questionnaire knowledge test. To briefly review, dimensionality was measured by the number of unique nutrition concepts produced by the elicitation ($M = 6.6$) and repertory grid ($M = 5.7$) procedures. Possible indices of abstraction were generated by classifying the unique nutrition responses from the elicitation and grid procedures as relatively abstract (M 's = 1.9 and 1.3) or concrete (M 's = 4.6 and 3.4). Two independent judges were reasonably consistent in their categorizations of the concepts as nutritional or not ($r = .85$) and as abstract/concrete ($r = .87$). Unfortunately, we had only a single index of articulation, the average number of category levels per nutrition concept ($M = 4.4$), as evidenced by the rep grid free sorting task.

Table 1 presents the relevant correlations between these constructs, in a multimethod-multitrait matrix format. First, note that concreteness, the number of concrete nutrition concepts, is highly correlated with dimensionality, the total number of nutrition concepts elicited ($r = .96$ for the free elicitation method and $r = .95$ for the rep grid procedure). Apparently, subjects who produced more unique nutrition concepts also produced many concrete concepts. Therefore, "concreteness" may not be useful for indicating the abstractness of a cognitive structure. Certainly, the number of abstract concepts has more face validity. It is possible that if finer distinctions between levels of abstraction/concreteness could have been made, the apparent redundancy would be eliminated or reduced. However, criteria for more finely discriminating between levels of abstraction are not clear to us. Because concreteness is essentially totally redundant with the dimensionality measure, in the present data at least, we will ignore most of the correlations with the concrete measure, although they are shown for completeness.

Next, consider the convergent and discriminant indices. The rep grid and free elicitation methods seem to converge

fairly well on the concepts of dimensionality and abstraction (r 's = .56 and .65, respectively, $p < .05$). The low off-diagonal values of .02 and .29 provide evidence of discriminant validity. Note also the dimensionality and abstract construct constructs are apparently positively related, as one might expect (r 's = .49 and .28 for free elicitation and rep grid, respectively). That is, as the dimensionality of cognitive structure increases, there is a tendency for it to become more abstract. Because only a single measure of articulation has been developed thus far, estimates of convergent and divergent validity are not possible. However, the low, negative relationships between articulation and the dimensionality and abstraction measures are quite consistent for both measurement methods. Although the small magnitude of these correlations do not allow confident theoretical interpretations, it seems logical to suppose that as the dimensions of a structure become more abstract, they also become less articulated. In sum, both the magnitude of these relationships and their general consistency, especially given the long time period between measures, provide support for the construct validity of the three characteristics of cognitive structure and the validity of the measures developed as indicators of those concepts.

What about the traditional paper-and-pencil knowledge test? As can be seen in Table 1, knowledge test scores are only weakly related to the other measures of cognitive structure. The test scores seem to relate more strongly with the rep grid measures, although this is only a weak tendency. At least all the relationships are positive, as would be expected if each measure is tapping nutrition knowledge structures. Clearly, however, the knowledge test is not measuring the same thing as the free elicitation and repertory grid methods.

Conclusions and Implications

In our opinion, sufficient evidence of convergent and

discriminant validity has been demonstrated to warrant additional work on these hypothesized cognitive structure constructs. The magnitude of the obtained relationships and their consistency are reasonable, although certainly not outstanding. The effect sizes obtained can be seen as a bit more encouraging when one considers that the subject sample was probably more homogeneous with respect to nutrition knowledge than the general population. Given the probable restriction of range in our indicators produced by this homogeneity, the obtained coefficients can be seen as even more respectable. In conclusion, then, the repertory grid and free elicitation procedures appear to be capable of producing valid indicators of two potentially important characteristics of cognitive structure--dimensionality and abstraction. Also, the other hypothesized attribute of cognitive structure, articulation, evidenced consistent relationships with the measures of both dimensionality and abstraction.

We are encouraged by these results and are conducting further investigations concerning the construct validity of these characteristics of cognitive structure. What should be the next steps in such a research program? Obviously, a replication of this study should be conducted. To increase power, such a replication should use more subjects, if possible. Moreover, it would be valuable to obtain subjects who possess wide ranges of nutrition knowledge. Increasing the variance for measures of nutrition cognitive structures should enhance the predicted relationships, compared to the present results, if the basic model is essentially valid.

A slightly different approach to construct validation could provide a somewhat stronger "test" of the validity of these measures. One could select subjects who on some a priori basis comprise two (relatively) extreme groups in terms of their knowledge about nutrition. For instance, one might use senior undergraduate nutrition majors and seniors who had never taken nutrition courses. Or, one could examine persons known to be highly concerned about their eating habits (health food advocates, e.g.) versus less concerned people (ordinary citizens). Presumably, such groups would differ dramatically in terms of their cognitive structures regarding nutrition. If so, valid measures of the major characteristics of knowledge structures should reflect these differences.

Eventually, future research must predict the effects that differing cognitive structures have on other cognitive variables and processes and must test those hypotheses empirically. For example, if someone has a complex cognitive structure for nutrition (high dimensionality, relatively abstract, well articulated), we might predict certain types of cognitive responses to a series of food ads containing nutrition information. Presumably, such a person's responses should differ from those produced by a different consumer with a shallow, simple cognitive structure for nutrition. Minimally, the former consumer should produce more nutritional cognitive responses. Probably, these responses would be more abstract or deeper in a semantic sense (Olson 1980). In contrast, the effects of differing cognitive structures on persuasibility (e.g., attitude and intention change) are less clear (see Marks and Olson 1981). To make such predictions, one must carefully examine the idiosyncratic content of stored knowledge and determine, among other things, the degree of discrepancy between the individual's pre-exposure beliefs and those presented in the message. Finally, differences in cognitive structures should be reflected by variation in decision-making processes. Here we might examine the amount of time taken, the number of attributes considered, and the optimality of the selected alternative, among other factors.

In conclusion, we hope to have stimulated at least some readers to undertake research that deals more directly with peoples' cognitive structures than typically has been done. Issues regarding cognitive structure are intrinsically

interesting, and they are important. Developing clearer ideas regarding the content and organization of cognitive structures seems likely to enhance our understanding of the other cognitive processes that are influenced by cognitive structure, and of cognitively-mediated behavior, too.

COGNITIVE MAPS AND SHOPPING CONVENIENCE

Sanford L. Grossbart, University of Nebraska
Balusu Rammohan, University of Nebraska

Abstract

The nature and functions of cognitive mapping and maps of large scale shopping areas are reviewed. A method of measuring cognitive maps is employed to study the possible bases for customers' beliefs regarding the convenience of shopping downtown. Results are presented which indicate that mapped information is related to various forms of shopping convenience.

Introduction

The central thesis of this paper is that beliefs regarding the convenience of shopping downtown are related to customers' cognitive maps of the downtown spatial environment. While multiple factors influence customers' patronage decisions, the issue of convenience is singled out for several reasons. Observers frequently mention the inconvenience of traveling to the area, parking and moving between stores as important reasons for the decline of downtown business in cities of all sizes. Moreover, the provision of "more convenient" physical plans and parking amenities represents a costly undertaking which is apparently beyond the capabilities or willingness of many individual businesses and city planning bodies. As such redevelopment designs have been drawn and debates concerning the sharing of costs required to provide increased convenience have continued, there has been a tendency to overlook the fact that customer beliefs about convenience are apt to be highly subjective and related to a set of largely unidentified determinants. The exploratory research described here was undertaken with the expectation that differences in customer's spatial images of the downtown, termed cognitive maps, would be related to beliefs about different forms of convenience. Evidence which supports this expectation, while obviously not addressing all aspects of downtown deficiencies, carries the important implication that providing customers with more adequate information about retail identities and functions may alter their beliefs about shopping convenience and, therefore, pose a less costly alternative than large-scale physical changes.

The Nature and Functions of Cognitive Mapping and Maps

Cognitive mapping is the mental process involved in acquiring, storing and manipulating information about spatial environments. As organized representations of portions of the environment, these maps are simplified models or mental images of complex physical reality (Downs and Stea 1977). Maps are formed in terms of places within places, e.g., stores within a downtown, whose perceived prominence, functional and symbolic meaning and use increase the likelihood of their mental representation. Information concerning these stores aids customers in understanding the spatial dimension of the shopping area. There are three basic sources for mapped information (Downs and Stea 1973). Direct experience, e.g., shopping and moving about the area, provides the opportunity for the integration of kinesthetic, visual, tactile and olfactory sensory information about store identities, activities, distances, locations and other aspects of a downtown. Vicarious sources which provide second hand spatial information may include friends, salespersons, media, street maps, Chamber of Commerce brochures, etc.

Finally, persons may form inferences by elaborating upon and augmenting the direct or vicarious information which they have acquired. For instance, information about the location and density of certain types of stores (such as fashion boutiques or antique shops), and may lead to inferences about the existence and character of other stores in that particular sub-area.

In a strict sense, the term cognitive mapping is somewhat misleading but is used because of its widespread employment in environmental psychology, geography and other disciplines involved in the study of environmental behavior. Recognizing the potential for confusion, theorists have made an effort to point out that affective and conative influences impact on the cognitive mapping process and on interpretations of cognitive maps (Downs and Stea 1973; Kaplan 1973). While considerable research interest has been devoted to the nature and function of cognitive maps (Stokols 1978; Moore 1979), with few exceptions (Mazze 1974; Mackay and Olshavsky 1975; Mittelstaedt, Grossbart and Curtis 1977) these subjects have received little attention in the field of consumer behavior. Consequently, it is hardly surprising that there has been limited recognition of the likelihood that shopping behavior, like other forms of spatial behavior, is a function of persons' cognitive maps of the spatial environment. Similarly, and of more immediate concern, there has been little acknowledgement of the influence of cognitive maps on different dimensions of retail images, such as those relating to convenience. These assertions develop from a perspective which suggests that shopping areas should be treated as places rather than objects (Mittelstaedt, Grossbart and Curtis 1977; Canter 1977).

As a place, the downtown represents a large scale surface whose complexity is a function of the number, frequency and distribution of information categories which are presented to customers. The physical and functional features of retail establishments are neither ubiquitous nor are they uniformly distributed -- they have instead locations on the surface. In every sense the area engulfs customers whose limited mobility, sensory capability, information processing ability, storage capacity and available time require them to develop simplified abstractions of the downtown. Individuals interact with the downtown in a distinctive and selective manner and with each transaction learning is likely to occur (Rosenberg 1965-66; Fatouros 1968). Mapping of the downtown occurs, in part, as customers receive imperfect multisensory information (Mehrabian and Russel 1974; Grossbart, Amedeo and Chinchin 1979; Downs and Stea 1977) from an uncertain and changing retail environment. Since shopping occurs at different times and varies in duration, the direct acquisition of information for mapping takes place over varying times and intervals.

From the diversity of direct experience, the vicariously related information and inferences, customers aggregate limited and imperfect impressions to form comprehensible representations of the downtown. The product of this process, the cognitive map, has been described as a network (Kaplan 1973) of organized beliefs (Downs and Stea 1973) about a large scale environment. The absence of a map, or, of certain stores within the map, may necessitate a series of personal inquiries, checking of printed information (e.g., the Yellow Pages), and/or the expenditure of the additional time and effort involved in search. In contrast, the existence of cognitive maps serve a variety of purposes. Maps allow customers to find things (e.g.,

merchandise, stores, sales, restaurants, etc.) as well as people (e.g., favored salespersons, providers of specific services, etc.) by providing indications of direction and distance. They also allow customers to gain an impression of where they are within the area and thus predict the stores, merchandise and activities which will be encountered as they move in different directions. As a result this network of beliefs can provide a basis for evaluating the consequences of various shopping behaviors (e.g., coming to the area, choosing routes for multipurpose trips, visiting certain stores, finding certain merchandise or services, etc.) Thus references to cognitive maps and consequent evaluation of maps allow customers to make a variety of shopping decisions.

Customer Convenience

Customer convenience has long been recognized as having an important influence on shoppers' evaluations of stores and shopping areas (Kelley 1958; Cox 1959; Downs 1961; Bender 1964). As a shopping cost, inconvenience has been identified as an economic and psychological expenditure and source of frustration and annoyance which is both traded-off with the price of goods and services and added to them to form the total price paid by customers (Crafton 1979). Given the acknowledged role of convenience in influencing customer decision making (Markin 1977), it is not surprising to find theoretical and empirical support for the inclusion of convenience as one of the evaluative criteria composing retail images (for a review, see Lindquist 1974-75). Beliefs regarding customer convenience have been shown to differ when retailer and customer perceptions are compared (Pathak, Crissy and Sweitzer 1974-75) and have been identified as being dependent on a set of largely unknown factors of spatial cognition and urban form (Downs 1970).

A review of the literature indicates support for the existence of five forms of shopping convenience. The most well known form is travel convenience, i.e., the perceived ease of making a trip to a shopping area (Kelley 1958; Downs 1961; Bender 1964; Rich and Portis 1964; Kunkel and Berry 1968). Parking convenience (Kelley 1958; Downs 1961; Rich and Portis 1964; Kelly and Stephenson 1967; Kunkel and Berry 1968; Downs 1970; Lindquist 1974-75) is frequently mentioned in discussions comparing the competitive strengths of downtowns and outlying shopping centers. Customer movement convenience (Cox 1959; Downs 1961; Kunkel and Berry 1968; Downs 1970) involves the ease of movement between stores while shopping. Aggregate convenience is a term used by Cox (1959, also see Bender 1964) to refer to the ease with which consumers come into physical contact in succession with a large variety of goods and services. Properly aggregated, clusters of goods and services follow the principle of efficient congestion by concentrating retailing offerings while avoiding dysfunctional traffic and congestion. Finally, merchandise display convenience (Cox 1959; Bender 1964; Rich and Portis 1964) provides customers with necessary cues which minimize undesirable search by enabling shoppers to locate merchandise for comparison, inspection or purchase. The minimization of undesirable search can be a critical factor in shopping since customers are likely to engage in more product evaluation when shopping effort is perceived as low (Harrell and Hutt 1976).

Cognitive Maps and Perceived Convenience

Given the selective spatial character of shopping behavior and the limitations inherent in customers' mapping capabilities, three pertinent characteristics should be evident in cognitive maps of the downtown. These maps are likely to be more selective and therefore less extensive than retailer-defined definitions of the area. Second, within the cognitively defined boundaries of the area, maps are likely

to be incomplete in that the identity, function and locations of all stores will not be represented. Finally, imperfect encoding of available sensory information, incorrect and misinterpreted vicarious information, and erroneous inferential augmentation and elaboration are likely to result in cognitive mapping errors. Of course, it would be naive to expect shopping behavior to be totally confined or limited by material included in cognitive maps. While there is sufficient evidence to suggest that map accuracy does vary among individuals (Stokols 1978; Moore 1979), the "goodness" of a cognitive map is best judged in terms of its usefulness as a guide to its possessor rather than in terms of its accuracy or detail (Kaplan 1973). Shoppers can, after all, supplement mapped information or correct misinformation by inquiry, search or trial and error. Prior to such supplementation or correction, however, they are likely to form beliefs about shopping convenience based on their beliefs regarding the identities, functions or offerings, and spatial distribution of retail facilities in the downtown. As they shop, they may supplement or correct their maps or even find desired facilities, merchandise or locations without altering their maps. Any of these acts, however, are likely to involve added effort and therefore decrease the perceived convenience of shopping.

Previous comments refer to general relations between mapped retail information and perceived convenience. Expectations for specific relationships are presented in Table 1. Absolute identity level refers to the number of correctly named and located facilities in a cognitive map while relative identity level refers to the proportion of correctly named and located facilities. Absolute and relative functional level have a similar meaning but refer to knowledge of the nature, predominant offerings, or activity of mapped establishments. The five forms of shopping convenience have been defined earlier.

TABLE 1
Pattern of Expected Relationships Between Forms of Shopping Convenience and Cognitive Map Characteristics

Cognitive Map Characteristics	Forms of Shopping Convenience				
	Travel	Parking	Customer Movement	Aggregate	Display
Absolute identity level	X			X	X
Relative identity level	X	X	X		X
Absolute functional level	X			X	X
Relative functional level	X	X	X		X

Identity and functional levels of maps should influence beliefs regarding travel convenience in two respects. As the absolute knowledge of identity and function increases, the general attractiveness of the area and the perceived convenience of making a shopping trip should also tend to increase. As relative knowledge of function and identity increase, there should be less probability of customers confusion and frustration during shopping trips, less perceived effort in shopping downtown and a consequent increase in perceived travel convenience.

Relative levels of identity and functional knowledge are associated with parking and customer movement convenience. As the proportion of correctly mapped retail information increases, customers are likely to be able to better plan their spatial movements and parking activities. Conversely, parking convenience is likely to decrease if customers' limited relative knowledge of the locations of facilities and functions leads them to make less efficient parking decisions. Likewise, decreasing relative knowledge of

identities and functions is likely to lead to increasing customer confusion and frustration and/or increased shopping efforts to locate stores, merchandise or services. Thus perceived ease of movement should tend to covary with both types of relative knowledge.

Absolute levels of identity and functional knowledge are expected to be related to perceived aggregate convenience. Under normal circumstances, increasing knowledge of facilities and their offerings should lead customers to infer the existence of a wide range of goods and service offerings in the downtown.

Finally, all four map characteristics should be related to beliefs regarding display convenience. As the absolute and relative knowledge of the identity and function of retail sites within the downtown increases, customers should be expected to have a clearer conception of a wider range of offerings, be less confused about the spatial distribution of available goods in the area and, therefore, be less dependent on display cues for this information. In contrast, those whose cognitive maps possess lower levels of knowledge should tend to rely more on display cues to supplement and correct mapped information. In the process they are likely to expend greater effort in utilizing display information. Consequently, customers who possess greater levels of knowledge and therefore place less frequent reliance on display cues should judge them to be easier to use than shoppers whose lack of knowledge leads them to substitute display cues for incomplete and incorrect mapped information.

Method

Site

This study dealt with the downtown area of a small mid-western city. The city's well established downtown retail base had operated successfully for years but it currently faces competition from outlying shopping centers. In recent years some downtown retailers have chosen to relocate in these shopping centers or move elsewhere.

Retailer Definition of Downtown

Interviews with representatives of the trade council and Chamber of Commerce provided information concerning the characteristics of downtown shoppers and a geographic definition of the shopping area in terms of the center and boundaries (i.e., the extent). Following these delineations an audit was done to ascertain the names, locations and functions of all facilities in and immediately surrounding the defined area. Using this information, two maps were prepared. The first was a base map showing possible streets and blocks that might be included in the downtown. The second was a reference map which indicated the names, functions and locations of facilities in addition to the information provided in the base map.

Sample

Prior market research indicated that the downtown's primary trade area included customers within a sixty mile radius of the city. Based on earlier estimates of the proportion of shoppers residing in different parts of the trade area, a geographically stratified sample of fifty-one adults was drawn from within the community and four other randomly selected areas within fifteen, thirty, forty-five and sixty miles of the city. Persons within these five designated areas were randomly selected and contacted by telephone to arrange inhome interviews. Respondents included adults who shopped in the downtown in the last year, lived at least two years in the trade area (thus affording them the opportunity to learn about the downtown), and were members of households in which no person had been employed by a downtown establishment. The

refusal rate among those who met the stated criteria was approximately ten percent and a check of respondent profiles indicated a sample which was representative of downtown shoppers.

Instrument

In addition to screening questions, which ensured that respondents met the criteria for inclusion in the sample, and demographic items to allow estimates of the sample's representativeness, the instrumentation was divided into two parts.

Scales. The first part contained a set of self-administered scales measuring convenience beliefs, shopping evaluation and shopping frequency. Statements regarding the convenience of traveling to the downtown to go shopping, finding convenient parking, the convenience of getting from one store to another, finding a variety of goods and services, and displays making it easy to see the goods and service offerings were ordered in a randomized manner. Each statement was accompanied by a seven-point scale (ranging from very unlikely to very likely) indicating the likelihood that the statement was true. Overall evaluation of shopping was measured in terms of a seven-point scale (ranging from very pleasant to very unpleasant) indicating the pleasantness of shopping downtown. Average monthly shopping frequency was also recorded.

Mapping Task. Part two contained the base map. Respondents mapping task initially consisted of drawing a line indicating the boundaries of the shopping area and placing an "X" at the intersection which they considered to be the center of the downtown. The last phase of mapping involved respondents description of what they believed to be on each blockside within the downtown in terms of name, function and location of places. The task represented a variation of the previously employed sketch map procedure (Lynch 1960; Downs and Stea 1977; Mittelstaedt et. al. 1977; Holahan and Dobrowolny 1978), which has been suggested as the most appropriate method of measuring cognitive maps (Jackle, Brunn and Roseman 1976).

The entire instrument was pretested prior to employment. The interviewer also recorded any comments made by respondents and, as a further precaution, began and ended each interview asking respondents to indicate their general thoughts about the downtown. Interviews averaged eighty minutes in length.

Coding and Analysis

Preliminary coding of maps involved recording the extent of the defined area (number of blockside), the number of facilities included and the perceived center of the area. Next, each facility located on a respondent's map was compared to the corresponding site on the reference map and coded in terms of whether or not the identification and indicated function were correct. Incomplete responses, i.e., those which mentioned only a facility's name or function or indicated that either was "unknown," were coded as incorrect with respect to the omitted or unknown information. Correctly identified facilities were counted to form the absolute identity level score for each map. Similarly, the correctly designated functions were counted to form the absolute functional level score. Relative identity and functional levels were computed, respectively, by dividing the number of correctly identified facilities and the number of correctly designated functions by the total number of perceived facilities.

The analysis was designed to reaffirm the general salience of convenience in customer evaluation and behavior and the selectivity of customer cognitive mapping prior to testing the expected associations between convenience beliefs and map characteristics. Analysis focused first on the correlation between beliefs regarding different forms of shopping

convenience and overall evaluation of shopping and shopping frequency. Significant, although not necessarily high, correlations were expected to reaffirm the general salience of convenience beliefs. A map summarizing customer definition of the area and the spatial distribution of perceived activity was then prepared. Next, retailer definition of the downtown was compared with cognitive map definitions in terms of extent, contents and perceived center. Finally the correlations between map characteristics and forms of shopping convenience were examined and compared to the expected pattern in Table 1. The nature of the analysis in this exploratory research was deemed to be appropriate prior to future multivariate investigations of the relationships:

Results

Respondents' comments before and after each interview made it clear that they were not unduly sensitized by the instrument, had not found it difficult to understand or follow instructions, and had not deduced the purpose of the study. Prior to the presentation of scales, when asked about their general thoughts regarding the downtown, almost all respondents made unaided references to multiple forms of shopping convenience.

Convenience, Overall Evaluation and Shopping Behavior

Beliefs regarding the five forms of shopping convenience were examined for their assumed relationships with customer evaluation and frequency of shopping downtown. Given other goods and service mix attributes (price, quality, etc.) which may influence shopping evaluation and behavior, it would be unreasonable to envisage extremely high correlations. However, it would be logical to expect more association between beliefs regarding convenience and evaluation of shopping experiences than with shopping frequency because of the number of additional variables, such as situational factors, which may influence shopping frequency. Results are presented in Table 2. All five forms of convenience are significantly related to overall evaluation of shopping downtown. As might be expected, beliefs concerning travel convenience have a lower correlation with evaluation than beliefs regarding other forms of convenience, which refer in a more direct sense to the experience of shopping in the area. Beliefs regarding each form of shopping convenience are also associated with customers' frequency of shopping downtown. In general, assumptions about the role of convenience related beliefs were substantiated.

TABLE 2
Correlations of Overall Evaluation of Shopping and Shopping Frequency with Forms of Shopping Convenience

Forms of Shopping Convenience	Overall Evaluation of Shopping Downtown	Frequency of Shopping Downtown
Travel	0.24 ^c	0.26 ^c
Parking	0.39 ^b	0.28 ^c

Aggregate	0.42 ^a	0.21 ^d
Display	0.54 ^a	0.22 ^d

^a p < .001 ^b p < .01 ^c p < .05 ^d p < .10

Retailer Versus Customer Definitions of Downtown

The selective nature of cognitive maps is reflected in the summary map in Figure 1 which presents the percentage of

respondents perceiving activities on each blockside in the downtown area. This summary map does not indicate the identity or functional level of customer maps; it merely shows the degree of general definition of perceived activities on the illustrated blocksides. The amount of general definition on blocksides along the edges of the map is either nonexistent or very low. The sub-area with the highest degree of definition is along 3rd Street bounded by Walnut and Locust. Moving out from this sub-area, the degree of definition declines slowly initially and then rapidly in all directions. From this summary map it is apparent that the downtown is perceived by customers as having a central core surrounded by increasingly declining activity (for further discussion of this phenomenon, see Mittelstaedt, Grossbart and Curtis 1977). While the summary map includes all blocksides on which customers perceived activities, it is actually somewhat smaller than the definition of the area provided by retailers. Retailers defined the downtown as extending over 280 blocksides, containing 311 facilities and having a center located at 3rd and Locust. An analysis of customer versus retailer definitions of the area revealed that (1) the ratio of the mean extent of customer maps to retailer defined extent was .28, (2) the ratio of the mean number of facilities perceived by customers to number defined by retailers was .16 and (3) thirty-seven percent of customers perceived the center of the downtown to be located at the intersection designated by retailers. Thus, on the average, customers defined the downtown as covering twenty-eight percent of the area as defined by retailers and containing sixteen percent of retailer-defined facilities while almost two-thirds of customers regarded the center of the downtown as being somewhere other than that indicated by retailers.

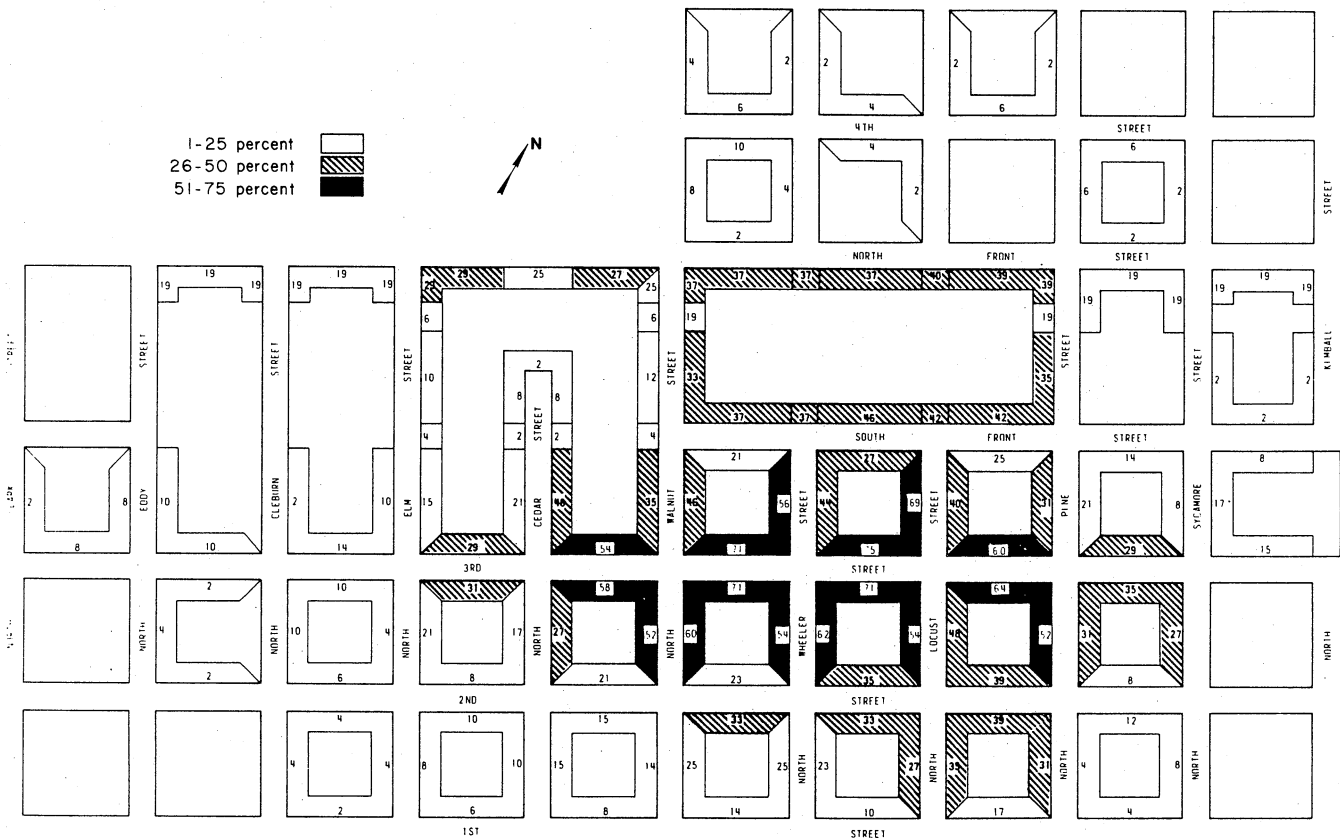

Map Characteristics and Beliefs Regarding Convenience

Correlations between map characteristics and beliefs regarding shopping convenience are presented in Table 3. The expected pattern of associations may be found in Table 1. Three of four predicted associations between map characteristics and beliefs concerning travel convenience are significant. All cognitive map measures, rather than just the two relative measures, are related to beliefs regarding parking convenience. The expected pattern of results are present for beliefs about customer movement, aggregate and display convenience. In the case of aggregate convenience, however, the relationships are inverse rather than direct. Comments before (by 50 percent of the sample) and after (by 79 percent) the structured portion of the interview made reference to downtown stores relocating elsewhere and thereby reducing the mix of available goods and services. It may be that general awareness of a diminution of the retail base coupled with absolute knowledge of the identity and functions of downtown establishments leads shoppers to believe that there is less likelihood of being provided with aggregate convenience.

Conclusions and Implications

In general, the results are consistent with predicted outcomes and the underlying rationalization regarding the function of cognitive maps in shopping. Nevertheless, simple correlations do not provide indications of causality. Further research in other cities with larger samples appears justified. As such investigations are conducted it will be possible to develop and test a multivariate causal model of cognitive mapping, shopping convenience and customer behavior. Still, the present findings underscore the potential usefulness of cognitive mapping theory and techniques to study customer beliefs about shopping areas. Moreover, they raise a fundamental question concerning whether the provision of more adequate retail information to shoppers might not alter their beliefs about convenience and, therefore, be a more efficient alternative than costly physical changes in downtown areas. While information may

A METHOD FOR DETERMINING THE SEQUENCING OF COGNITIVE PROCESSES IN JUDGMENT:
ORDER EFFECTS ON REACTION TIMES¹

John G. Lynch, University of Florida

Abstract

This paper proposes a method for testing hypotheses asserting that to make a judgment, *y*, the consumer must first make another implicit judgment, *x*. The method examines reaction times for subjects to explicitly judge both *x* and *y*, varying the order and the temporal spacing of the 2 judgments. An illustrative experiment is reported that used the method to study the "false consensus effect"--the tendency for persons to attribute their own opinions and behavior to others. Because of an apparatus problem, faith should not be placed in the data. They are presented only to demonstrate the data analysis procedures employed by the method.

Testing Models of Cognitive Process

It is often the case that theories in consumer behavior and related disciplines postulate that one judgment, *y*, is mediated by another implicit judgment, *x*. For example, attribution theory (Calder & Burnkrant 1977) postulates that to judge whether a consumer's purchase of a particular brand tells us something about his or her personal dispositions, one must first make a subjective assessment of whether most consumers would have made a similar choice in that situation. However, a judgment of the commonness of choosing a particular brand does not necessarily lead to a subsequent judgment of the personal characteristics of those who buy it.

A question arises as to how a researcher might test a theory that postulates the sort of fixed sequence of mental processes described above (*y* does not necessarily follow *x*, but *y* is necessarily preceded by *x*). Typically, the best one can do is to marshal evidence that *x* and *y* are highly correlated--an unsatisfactory solution to the problem. One could try to improve upon correlation by establishing that *x* precedes *y* in time. Unfortunately, if *x* and *y* are steps in a sequence of cognitive processes, they may occur too close together in time to be able to easily establish the temporal precedence of *x*. An alternative approach would be to manipulate *x* and show predicted effects on *y*. However, this would show only that *x* has effect on *y*. It would not show that a judgment of *x* is autonomously made whenever *y* is judged, so that *x* is a necessary precondition of *y*. In short, the standard tools of casual inference fail to provide the leverage one needs to test hypothesized relationships between mental events *x* and *y* such that a judgment of *y* implies that one must first make an implicit judgment of *x*--yet such theories are not at all uncommon in information processing research. This paper will propose a method for dealing with this general class of problems by examining order effects on latency to respond to questions about *x* and *y*. To illustrate the application of the

method, a flawed experiment is presented that concerns the mental processes underlying judgments of the opinions and preferences of "most people" or "the average person."

Self vs. Other in Consumer Inference-making and Judgment

A pervasive theme in theories of consumer behavior is that a consumer's perceptions and behavior are affected by two broad classes of variables: a) his or her personal beliefs, attitudes, and preferences, and b) perceptions of the beliefs, attitudes, and preferences of generalized and specific others. For example, Burnkrant and Cousineau (1975) contrast informational social influence, in which a person is privately persuaded by the arguments of others, with normative social influences, in which one complies with the judgment of others while remaining privately unconvinced, because of one's concern for how the others would react to one's compliance or noncompliance. A similar self/other duality appears in attribution theory (Calder & Burnkrant 1977), which claims that the perceived cause of a consumer's behavior depends upon how consistent her actions are with the sort of behavior one would expect of most people or the "average person" in a similar situation. Fishbein and Ajzen's (1975) model asserts that a consumer's intention to buy a product is influenced by his personal attitude toward the act of buying the product, and his perception of whether important others think he should or should not make the purchase. Belk's (1976) analysis of gift-giving could be loosely construed as suggesting that when a consumer has no explicit knowledge of the recipient's preferences, he might first decide whether he personally liked the gift, then try to assess whether his tastes and the recipient's were likely to be similar in the product class being considered.

False Consensus

Germane to the discussion above is work by Ross and his colleagues (Ross 1977; Ross, Greene, and House 1977), showing that individuals tend to over-estimate the proportion of others who would make the same behavioral choices they would make (e.g., watch a favorite TV show or prefer a particular brand of coffee), and to underestimate the commonness of choices contrary to their own. Ross et al have dubbed this tendency the "false consensus effect." These researchers placed subjects in a variety of imaginary and real situations in which they were forced to choose between two alternatives, A and B. Subjects were asked to estimate the percentage of persons in the general population who would choose each option, and to indicate which choice they themselves would make. Results showed that both persons who chose A and those who chose B believed themselves to be in the majority. Other experiments showed that the false consensus effect extended into the belief domain. Subjects attributed opinions to the "average person" that tended to agree with their own.

Possible Sources of False Consensus

One might be tempted to interpret the false consensus effect as evidence that judgments of what others think are based upon one's own opinions--to judge what the average person would say, one considers one's own opinion, then generalizes from oneself to the average person. Such a conclusion would be unwarranted, since previous research on the false consensus effect was purely correlational. The correlation between (*x*) one's own choice of A or B and (*y*) the perceived commonness of choosing A might, like any correlation, be

taken as evidence that a) x caused y, that b) y caused x, c) that both were influenced by some third factor, z, or d) that x and y are part of some bi-directional causal system. Below are some of Ross et al's (1977) speculations about possible sources of false consensus. In the discussion that follows, it should be remembered that "cause" refers to "implicational causation"--x causes y if a judgment of y implies that the person must first activate knowledge structures pertaining to x.

"Independent Judgment" Explanations ($z \rightarrow x$, and $z \rightarrow y$). A number of explanations of the false consensus effect are consistent with an "independent judgment" model. One such account involves selective exposure. Ross et al note that we tend to associate with friends who share our beliefs and values to a greater extent than these are shared in the general population. Our friends do behave as we do in many instances. The false consensus effect, then, may reflect the fact that our experience leads us to see greater homogeneity in the world than actually exists, rather than any intentional or unintentional distortion of one's social reality to agree with one's own opinions or behavior. This explanation is consistent with an "independent judgment" model because a judgment of one's own opinion and a judgment of the "average person's" opinion activate independent cognitions. A person need not consider his or her own opinion to judge that of the average person, nor does a judgment of one's own opinion necessitate the activation of knowledge structures about what others think.

"Self-referent Inference" Explanations ($x \rightarrow y$). A second family of causal accounts of the false consensus effect suggests that perceptions of the commonness of various behaviors and opinions are the product of the subject's own choice of behavior or opinion. In general, information about oneself is more extensive and better integrated than information about others, especially if it is tied to an elaborate self-schema (Markus 1977). Self-schemata facilitate both the encoding of new information and the retrieval of information already stored in memory. For these reasons, it may well be that consumers use their own behavior, opinions, etc., as a basis for making judgments of the opinions of generalized and (probably to a lesser extent) of specific others.

"Other-referent Inference" Explanations ($y \rightarrow x$). A third possibility is that judgments of one's own opinions or preferences are based upon a consideration of what generalized or specific others think. For example, in a choice situation that is fairly novel, a consumer may search for information in memory about what relevant others thought or did in similar situations. Or, if questioned about one's opinion about a topic about which little is known, one may rely on information in memory about what some other person had said about it. Thus, a judgment of one's own opinion might require the activation of cognitions pertaining to what others have said or would say.

A Method for Assessing Implicational Causation

Based upon the evidence presented by Ross et al (1977), any one of the causal mechanisms discussed above might plausibly explain the false consensus effect. Of course, a complete explanation might include several of these mechanisms, and bi-directional causality may be involved. This paper proposes a method for deducing the primary direction of causality underlying the correlation between subjects' choices and their consensus estimates. The method is generally applicable to problems in which two judgments, x and y (in this case, one's own agreement or disagreement with opinion statements and estimates of whether others would agree) are found to be correlated, and one is concerned with whether one is causal in the sense that an implicit judgment of x must be made in order to make a judgment of y. The method involves an analysis of the time it takes a subject to answer questions about x and y as a function of the order in which the questions and the delay

between the two questions.

In the experiment to be reported, subjects were shown a series of opinion statements, one by one, on a computer terminal. Each was presented twice during the experiment, a) once preceded by an instruction to judge one's personal opinion (which will be hereafter called a "Self" judgment) and b) once preceded by an instruction to judge the average University of Illinois student's opinion (which will be called an "Other" judgment). Subjects responded to each statement by pressing either a key marked "AGREE" or one marked "DISAGREE." Let us consider what processes of judgment would be predicted in the various conditions by our 3 causal "theories," and how reaction times would be affected by these processes.

Components of Reaction Times for 3 Theories

The "self-referent inference" model decomposes the time to make a Self judgment into 2 parts: time to read and Comprehend the opinion statement (designated c) and time to retrieve and integrate knowledge relevant to determining Self's opinion (designated s).² A judgment of Other's opinion is assumed to require both of these same stages (c + s), plus a third stage during which the subject Generalizes from Self to Other (designated g_{os}). This last stage may involve testing for instances of disagreement, or deciding whether one's opinion about the relevant issue is likely to be typical.

The "other-referent inference" model follows a similar logic. Here a judgment of Other's opinion is assumed to involve a 2-stage process of reading and Comprehending the opinion statement (c), and retrieving and integrating knowledge pertaining to Other's opinion (designated o). The judgment of Self's opinion is assumed to involve a 3-step process: the same 2 stages (c + o) assumed to be required to judge Other's opinion, plus a 3rd stage involving Generalization from Other to Self (g_{os}).

The "independent judgment" theory concurs with the self-referent theory's account of Self judgments, and with the other-referent theory's account of Other judgments. That is, Self judgments require one to read and Comprehend the opinion statement, then retrieve and integrate knowledge relevant to judging Self's opinion (total reaction time = c + s). Other judgments also require 2 stages: a stage entailing the reading and Comprehension of the opinion statement, and one involving the retrieval and integration of knowledge pertaining to Other's opinion (reaction time = c + o).

Given the 3 different process accounts of how one judges one's own or the average person's opinion, a method to competitively support one of the models was sought. The problem was attacked by measuring latencies to respond "agree" or "disagree" to opinion statements. a) Subjects made both "Self" and "Other" judgments of each statement, but b) for half the statements, Self judgments were made prior to Other judgments, and the remaining statements were judged in the order Other First, Self Second, and c) the First and Second judgment of each opinion statement were separated by either a Short Delay or a Long Delay. As will be seen, the use of this experimental design with a dependent measure of reaction time permits a clear discrimination among the self-referent, other-referent, and independent judgment accounts of Self and Other judgments. Following is a discussion of the rationale underlying the "order effects or reaction times" paradigm in the general case.

²A third component, motor response time to physically execute a keypress, is assumed by all 3 theories to be constant across experimental conditions, so it will be ignored.

Logic of the "Order Effects on Reaction Times" Paradigm in the General Case

Suppose that a judgment of y requires an implicit determination of x, plus an additional stage like our Generalization stage, (g_{xy}), whereas a judgment of x requires only the former stage. If so, judging either x or y at time 1 (First judgment) will facilitate (i.e., reduce the latency of) making the opposite judgment at time 2 (Second judgment, Short Delay) or at time 3 (Second judgment, Long Delay). The facilitating effect results because, in making the Second judgment, the subject need not retrieve and integrate information pertaining to x, but may simply retrieve the integrated determination of x from memory. The average magnitude of the facilitating effect depends upon the likelihood that the subject will be able to (a) successfully retrieve the integrated determination of x, rather than (b) repeat the entire process of retrieving and integrating knowledge about x. The likelihood of being able to follow the shorter path (a) is an interactive function of 2 factors: 1) The delay between the First and Second elements of x-y or y-x pairs. If the delay is short, the integrated determination of x is virtually certain to be in short term memory, enabling the subject to follow path (a). In Long Delay conditions, though, it is less than certain that subjects will be able to retrieve the integrated determination of x from long term memory. 2) In Long Delay conditions, then, the probability of following the shorter path (a) on the Second judgment is positively related to the degree of elaboration of x required by the First judgment. A y-first judgment requires one to judge x, then process x further, whereas an x-first judgment requires no further processing after x has been determined. By a depth of processing rationale (Craik & Lockhart 1972; Craik & Tulving 1975), an x-First judgment should not be as helpful to a y-Second Long Delay judgment as a y-First judgment would be to an x-Second Long Delay judgment. The upshot of this is that the difference between Short and Long Delay versions of an x-Second judgment should be smaller than the difference between Short and Long Delay versions of a y-Second judgment.

Complicating this analysis somewhat is the fact that Second judgments would be expected to be faster than First judgments solely on the basis of practice effects on the speed of the reading and Comprehension (c) stage. This stage would be postulated to be faster for Second judgments made at time 2 (c_2 , occurring in Short Delay conditions) than for First judgments made at time 1 (c_1). By time 3, though, some of the benefit of prior exposure to the opinion statement should have dissipated, so c_3 (in Second judgments, Long Delay conditions) should be of intermediate length (i.e., $c_1 > c_3 > c_2$). The assumptions above allow us to derive predictions for the 3 theories of the false consensus effect.

Self-referent Theory. The self referent theory's predictions can be summarized briefly by referring to Table 1:

1. A main effect of judgment type should occur. Other judgments should take longer than Self judgments, mainly because the former involve an additional processing step of Generalizing from Self to Other (g_{so}).

2. A main effect of ordinal position should occur. First judgments of an opinion statement should take longer than Second judgments for two reasons: because of the greater Comprehension time (c) and the greater time to determine Self's opinion (s) associated with First judgments in a (Self-Other or Other-Self) pair.

3. If only Second judgments are analyzed, a significant interaction of opinion judged (Self vs. Other) and Delay should be observed. Based upon a depth of processing rationale, Other Second judgments should be more adversely affected by a long delay than should Self Second judgments, so $s_1 > s_3'' > s_3' > s_2$ in Table 1.

TABLE 1

Components of Reaction times predicted by "self-referent" "other-referent" and "independent judgment" models of implicational causation underlying the false consensus effect.

Self-referent

	Short Delay		Long Delay	
	Self Judgment Time 1	Other Judgment Time 1	Self Judgment Time 1	Other Judgment Time 1
First Judgment	$c_1 + s_1$	$c_1 + s_1 + g_{so}$	$c_1 + s_1$	$c_1 + s_1 + g_{so}$
Second Judgment	Time 2 $c_2 + s_2$	Time 2 $c_2 + s_2 + g_{so}$	Time 3 $c_3 + s_3'$	Time 3 $c_3 + s_3'' + g_{so}$

- c_1 : reading and comprehension time, first presentation.
- c_2 : reading and comprehension time, second presentation after short delay.
- c_3 : reading and comprehension time, second presentation after long delay ($c_1 > c_3 > c_2$).
- s_1 : time to retrieve and integrate self-relevant information to make Self judgment.
- s_2 : time to retrieve integrated Self judgment from short term memory.
- s_3' : average length of a stochastic process whereby subject either retrieves integrated Self judgment from long term memory, or repeats process s_1 .
- s_3'' : same as s_3' , except probability of having to repeat process s_1 is higher ($s_1 > s_3'' > s_3 > s_2$).
- g_{so} : time to generalize from Self to Other (infer implications of Self judgment for Other judgment).

Other-referent

	Short Delay		Long Delay	
	Self Judgment Time 1	Other Judgment Time 1	Self Judgment Time 1	Other Judgment Time 1
First Judgment	$c_1 + o_1 + g_{os}$	$c_1 + o_1$	$c_1 + o_1 + g_{os}$	$c_1 + o_1$
Second Judgment	Time 2 $c_2 + o_2 + g_{os}$	Time 2 $c_2 + o_2$	Time 3 $c_3 + o_3'' + g_{os}$	Time 3 $c_3 + o_3'$

- c_1, c_2 , and c_3 : same as above.
- o_1 : time to retrieve and integrate other-relevant information to make Other judgment.
- o_2 : time to retrieve integrated Other judgment from short term memory.
- o_3' : average length of a stochastic process whereby subject either retrieves integrated Other judgment from long term memory or repeats process o_1 .
- o_3'' : same as o_3' , except probability of having to repeat process o_1 is higher, ($o_1 > o_3'' > o_3 > o_2$).
- g_{os} : time to generalize from Other to Self.

Independent Judgment

	Self Judgment Time 1	Other Judgment Time 1	Self Judgment Time 1	Other Judgment Time 1
	First Judgment	$c_1 + s_1$	$c_1 + o_1$	$c_1 + s_1$
Second Judgment	Time 2 $c_2 + s_1$	Time 2 $c_2 + o_1$	Time 3 $c_3 + s_1$	Time 3 $c_3 + o_1$

- c_1, c_2 and c_3 : same as above
- o_1 : same as above (time to retrieve and integrate other-relevant information to make Other judgment).
- s_1 : same as above (time to retrieve and integrate self-relevant information to make Self judgment).

Other-referent Theory. Based upon a logic similar to that used to derive predictions of the self-referent theory, the following predictions of the other-referent model can be deduced, as shown in Table 1:

1. A main effect of opinion judged should occur. Self judgments should take longer than Other judgments, mainly because the former require an additional step of generalizing from Other to Self (g_{os}).
2. A main effect of ordinal position is predicted. First judgments of an opinion statement should take longer than Second judgments because of the greater Comprehension time (c) and greater time to determine Other's opinion (o) associated with First judgments.
3. By a depth of processing rationale, one can predict that the difference in RT between Self Second, Long Delay and Self Second, Short Delay cells should be greater than the difference between Other Second, Long Delay and Other Second, Short Delay cells ($o_1 > o_3^1 > o_3^2 > o_2$).

Independent Judgment Model. According to the independent judgment theory, knowledge relevant to determining one's own opinion and that relevant to determining Other's opinion exist in separate locations in memory, although both may have been influenced by some common third factor or complex of factors when originally stored. Self judgments are assumed to require subjects to Comprehend the opinion statement (c), then retrieve and integrate knowledge pertaining to Self's opinion (s). Other judgments are assumed to require a Comprehension stage (c), plus a stage involving the retrieval and integration of knowledge pertaining to Other's opinion (o). Retrieving and integrating knowledge relevant to making a Self judgment would not facilitate a later Other judgment, nor would the reverse be true. As shown in Table 1, Second judgments would be faster than First judgments simply because of the shorter time it takes to read and Comprehend (c) the opinion statement the second time around.

1. It is unclear whether a main effect of judgment type should occur. If time to retrieve and integrate information pertaining to Self's opinion (s) is less (or greater) than the time to retrieve and integrate knowledge pertaining to Other's opinion (o), a main effect will result.
2. A main effect of ordinal position will result, solely because of the greater time needed to read and Comprehend (c) the opinion statement during First judgments than during Second judgment.
3. When only Second judgments are analyzed, there should be no interaction between judgment type (Self vs. Other) and Delay.³

³These assertions assume that knowledge structures pertaining to Self's opinion and those pertaining to Other's opinion are completely independent. It is possible, though, that the basic idea underlying the independent judgment model is correct--Self judgments require no implicit consideration of Other's opinion, nor is the reverse true--but cognitions about certain facts must be activated whether one is judging one's own opinion or that of the average student. Such a quasi-independent judgment model makes relatively complicated predictions (see Lynch and Shoben, in preparation) not germane to the application of the order effects on reaction times paradigm in most consumer information processing settings. Hence, it will not be discussed further.

Method

Overview

In the present experiment, 66 undergraduate subjects were seated at cathode ray tube (CRT) computer terminals, on which a series of 32 opinion statements was presented. The statements concerned a variety of topics: energy (e.g., "Nuclear power is too dangerous to be a desirable source of energy"), consumer products ("Most breakfast cereals are worthless from a nutritional standpoint"), leisure activities ("It is more enjoyable to read a book than to watch television"), etc. Each statement was presented twice, a) once preceded by an instruction to judge "YOUR PERSONAL OPINION" ("Self" judgment), and b) once by an instruction to judge the "AVERAGE U OF I STUDENT'S OPINION" ("Other's judgment), for a total of 64 judgments. Subjects responded to each statement by pressing either a key marked "AGREE" or one marked "DISAGREE" as quickly as possible while still maintaining a high level of accuracy. Both latency to respond and the response itself were recorded for each trial. Half of the opinion statement pairs were presented in the order Self First, Other Second, and the other half were presented in the order Other First, Self Second. Additionally, the Second judgment in a given pair was separated from the First by either a Short Delay (1-5 trials) or a Long Delay (separated from the First member of the pair by an interpolated task).

The design, then was an Opinion Judged (Self vs. Other) x Order of Judgment (Self First, Other Second vs. Other First, Self Second) x Delay (Short vs. Long) within subjects design, with 8 items randomly nested in each Order x Delay condition. A different random nesting of items was used for each subject. To simplify the exposition of the experiment, it will be treated as an Opinion Judged x Ordinal Position (First vs. Second) x Delay factorial.

Procedure

Subjects, run in groups of 3 to 5, were told that the experiment was concerned with a) whether they personally agreed or disagreed with each of a set of opinion items, and b) whether they thought that the average student at the University of Illinois agreed or disagreed with the same statements. It was explained that 32 opinion statements would be judged once in each condition, for a total of 64 judgments, but that the order of these judgments would be "scrambled."

Each trial was structured so that an instruction phrase flashed onto the screen, telling the subject to judge either "YOUR PERSONAL OPINION" or "AVERAGE U OF I STUDENT'S OPINION" on the upcoming trial. After subjects had read the instruction phrase, they pressed the space bar on their keyboard. This action caused the instruction phrase to be erased, and an opinion statement to be written on the screen. Subjects were told to read the opinion statement as quickly as possible, to determine what they believed to be the correct response, and to press the appropriate key. Subjects were told that not only were their answers being recorded, but also the time it took them to respond. They were instructed to "respond as quickly as possible without sacrificing accuracy."⁴

⁴Cognitive psychologists employing reaction time as a dependent variable typically give subjects similar instructions to discourage them from trading off speed of response for accuracy. In applications in which one can verify the correctness of a subject's responses, it is imperative that differences in mean RT among experimental conditions are not spuriously caused by differential levels of accuracy (Pachella 1974). In the present context, however, there is no objective basis for assessing the "accuracy" of subjects' judgments, nor is it clear what "accuracy" might mean if it could be assessed.

The experimental session began with 8 practice trials, during which subjects were given feedback about their reaction times. If no questions arose, the practice trials were followed by 48 experimental trials, during which no RT feedback was given. After these trials (all short delay trials, plus the Self First and Other First trials in the long delay condition), subjects performed a 15 minute interpolated task, then completed the final block of 16 long-delay trials, again with RT feedback. Upon completion of the experiment, subjects were thoroughly debriefed and informally questioned about their processing strategies.

Procedural limitations. The experiment described was flawed by a problem with the apparatus. Although the computer was programmed to generate a different random assignment of opinion statements to experimental conditions for each subject, there is evidence that randomness was not achieved. A chi-square test of association between the 32 opinion statements and experimental conditions was significant at $p < .001$. Thus, differences in cell means may be attributable to differences in the content of the opinion statements that appeared in those cells. The results of the experiment are presented for illustrative purposes only, and should not be taken to be empirically valid.

Results and Discussion

Reaction times, with the additive effects of items and answers partialled out, were analyzed in a Subjects x Opinion Judged x Order (Self First, Other Second vs. Other First, Self Second) x Delay x Items (nested in Subjects, Order, and Delay) ($66 \times 2 \times 2 \times 2 \times 8$) completely within subjects analysis of variance. Items as well as subjects were considered random, in keeping with Clark's (1973) contention that linguistic materials must be treated as random. Data will be reported, however, as an Opinion Judged x Ordinal Position (First vs. Second) x Delay completely within S factorial. Mean reaction times in milliseconds are shown in Table 2.

TABLE 2

Effects of Opinion Judged (Self vs. Other), Ordinal Position (First vs. Second), and Delay (short vs. long) on Reaction Times (in msec) to answer "agree" or "disagree" to opinion statements.

	Short Delay Between 1st & 2nd Judgment		Long Delay Between 1st & 2nd Judgment	
	Self Judgment	Other Judgment	Self Judgment	Other Judgment
First Judgment	3922	4064	3982	4083
Second Judgment	3130	3134	3171	3292

Overall, Self Judgments were faster ($M = 3551$ msec) than Other judgments ($M = 3642$ msec), $F(1,65) = 8.84$ $p < .01$. Thus the data appear to be consistent with either the self-reference model or the independent judgment model, but not with the other-referent model. Thus the data appear to be consistent with either the self-reference model or the independent judgment model, but not with the other-referent model. Even so, one might ask whether averaging across subjects obscures individual differences in processing strategies. Perhaps some small subgroup of subjects made judgments consistent with an other referent process, using their knowledge of what the average Other might say to make Self judgments. If so, ordinal violations of the self-reference theory's

prediction that Self First RTs should be faster than Other First RTs should be associated with ordinal violations of the prediction that Self Second RTs should be faster than those for Other Second judgments. A chi-square test of the independence of these violations in individual subject data revealed no evidence of contingency ($\chi^2(1) = 1.36$, $p > .10$). Ordinal patterns in the data, then, suggest that subjects used a common cognitive process, although they apparently differ in the time they devoted to the various stages in this process. Significant Subjects x Ordinal Position (First vs. Second), and Subjects x Ordinal Position x Delay interactions ($F(65,1848) = 2.70$ and 1.56 ($p < .001$), respectively), suggest such individual differences. The data discussed up to this point allow the rejection of the other referent theory and seem to support either the self-reference model or the independent judgment model.

Inspection of the data in Table 2 reveals that Other Second RTs show a 158 msec difference between the short and long delay conditions, while Self Second RTs show only a 41 msec increase, consistent with the self-reference, depth of processing theory. A statistical test of this difference requires that only Second judgments be analyzed in a Subjects x Opinion Judged x Delay x Items (nested in Subjects, Opinion Judged and Delay) ANOVA. The critical interaction does not reach statistical significance, $F(1,65) = 2.45$ $p > .05$. If this experiment were not flawed by non-random assignment of items to experimental conditions, one would probably prefer the independent judgment model to the self-referent model based on these data.

Methodological Issues in Employing the Order Effects Paradigm

One problem of the "order effects on reaction times" paradigm as proposed is that a causal theory (in this case, self-reference) and an independent judgment model make different predictions in only one cell out of 8. Given this high variability inherent in reaction times to consumer stimuli, it is difficult to generate the kind of statistical power that is needed to discriminate two theories whose predictions are so similar. This would have been a problem in the experiment reported, had the data been taken seriously.

A second drawback of the paradigm is conceptual. To distinguish a causal theory (like self-reference) from an independent judgment model, one has to assume a "depth of processing" notion. Cognitive theorists have recently expressed doubts about the usefulness of Craik & Lockhart's (1972) levels of processing construct (cf. Baddeley 1978), and therefore, the use of the construct in the paradigm proposed by this paper may be unwarranted. To generate the predictions of the self-reference theory, it was assumed that deeper processing of one's own opinion occurred in Other First judgments (in which one implicitly judges Self's opinion, then decides whether it would generalize to others) than in Self First judgments (in which one implicitly judges Self's opinion, then overtly reports one's judgment). Lynch and Shoben (in preparation) discuss methods for testing such assumptions.

Conclusions

Despite the unresolved problems associated with using the "order effects on reaction times" paradigm, it seems uniquely suited to testing process models that postulate

that a judgment of y is mediated by an implicit judgment of x. Following are some examples of issues in consumer information processing that could be investigated through the use of the paradigm: (a) Fishbein and Ajzen's (1975) assumption that a judgment of behavioral intention implicitly involves the consideration by subjects of whether they think the behavior is good or bad, and of whether most people who are important to them think that they should perform the behavior. (b) The assumption of certain "brand-based" choice theories (see Bettman 1979, for examples) that choice from among a set of alternative brands requires overall evaluations of the brands to be made. (c) Hypotheses about the effects of inferential beliefs on evaluations of products (cf. Cohen, Miniard and Dickson 1979).

Researchers who attempt to use this general paradigm will encounter complications that are unique to the particular cognitive process and structure assumptions of the theory being tested. If one exercises care and creativity, though, the general approach of analyzing RTs to answer questions about each stage in a hypothesized chain of mental events as a function of the order of the questions and the delay separating the questions promises to be a powerful aid to the study of consumer information processing.

THE MODERATING EFFECTS OF COGNITIVE COMPLEXITY AND PRIOR PRODUCT FAMILIARITY ON THE PREDICTIVE ABILITY OF
SELECTED MULTI-ATTRIBUTE CHOICE MODELS FOR THREE CONSUMER PRODUCTS

Chin Tiong Tan, University of Singapore
Ira J. Dolich, University of Nebraska-Lincoln

Abstract

Respondents were classified according to their levels of cognitive complexity and product familiarity with three consumer products: automobiles, apartments, and toilet soaps. Using repeated measures and the repertory grid technique with ten brands and ten dimensions for each product class, five multi-attribute models are tested for predictive accuracy of rank order brand preferences. Three sets of 2x2x5 ANOVA studies showed significant systematic relationships between type of model and level of cognitive complexity and significant differences attributed to models across all products and to cognitive complexity for two of the three products.

Introduction and Theoretical Background

Multi-attribute choice models have been used in marketing to understand a host of buying related behavior such as attitude structure and judgment. Considerable effort has been devoted to using these models to predict brand preferences or choices.

Several exploratory studies (Park and Sheth 1975, Park 1976, and Menasco 1976) have attempted to identify selected individual characteristics or situational variables that may influence model usage and to investigate how these characteristics and variables affect judgment. Such a research direction should be encouraged, as it enhances an in-depth understanding of the interaction between brand choice, individual characteristics and situational differences.

The notion that a person acquires product familiarity while progressing through different stages of the learning curve is well documented in the consumer behavior literature (Howard and Sheth 1969). Sheth and Raju (1973) further proposed that different choice models, some more complicated than others, may be used at these different learning stages. In other words, consumers with different levels of familiarity with a product may rely on different types of brand choice models. This issue of product familiarity and use of choice model is a major consideration of the present study.

Marketers have made numerous attempts to link individual characteristics such as personality variables to buying behavior. In this study, the personality variable of interest is the complexity-simplicity of one's cognitive structure. Treating one's cognitive style as a personality structure is common in psychology (Schroder 1971), and its relationship with processing behavior is well documented in the works of Schroder, Driver and Streufert (1967). In that tradition, this personality characteristic is used as a moderating variable to examine its effect on the prediction of choice models.

This study centers on three specific consumer behavior issues: personality traits, choice models and familiarity with products. The major research objectives are to test propositions about the moderating effects of cognitive complexity and product familiarity on brand preferences derived from multi-attribute choice models.

Cognitive Complexity

Cognitive structure is viewed as a system of attributes or dimensions which form the basis of one's perceptual and judgmental processes. Kelly (1955), Bieri et al. (1966), and Schroder et al. (1967) showed that persons differ in cognitive structure and that such differences result in response variations. The relationships and interdependencies of dimensions within these systems bring about certain properties or characteristics that are considered unique to a person. Cognitive complexity is one such characteristic.

Cognitive complexity has been defined differently by psychologists (refer to Bieri (1971) for a review). The present study adopts the definition of Bieri (1955)-namely, the extent to which a person uses dimensions in a differentiated manner to construe objects. A complex person evaluates objects in a more multi-dimensional way and has a more differentiated set of dimensions available than does a simple person.

Psychologists have found cognitive complexity to mediate a wide range of behaviors such as attitude change (Lundy and Berkowitz 1957), information processing (Petronkon and Perlin 1970), salience of dimensions (Mueller 1974), and stereotyping (Koenig and King 1962). Marketers have recently investigated the construct. Among them, Park and Sheth (1975) found mixed results with the effect of cognitive complexity on choice behavior. The present study re-examines how cognitive complexity affects accuracy of prediction for several judgment models.

Product Familiarity

The extent to which a person is familiar with a product class depends largely on factors such as prior knowledge, usage, and purchase of brands in the product class. Marketers conceptualize one's familiarity to be a multi-dimensional concept comprised of elements such as awareness, knowledge, and actual usage of brands from the product class. Thus far, empirical studies on prior familiarity with products have been limited. Park (1976) found it to influence types of judgmental rules. However, another study showed familiarity to have little effect on brand preferences (Monroe 1976). The present study investigates how one's prior product familiarity may affect multi-attribute choice model efficiencies in predicting brand preferences.

Choice Models

Most of the marketing studies utilizing multi-attribute choice models disregarded individual differences and situational variations which might affect their usage. It is only recently that marketing researchers have begun to look to individual and situational differences as causes of the poor results found in some studies. Sheth and Raju (1973) have postulated that different processing rules for brand choices are used in different contexts. If such is the case, multi-attribute models, such as Fishbein's (1967) and Rosenberg's (1956), when used across different product classes for all types of consumers, would inevitably lead to weak results in some instances. The weighted linear-compensatory rule of their models cannot be assumed to hold for all buyers for all purchases.

The generalized model assumes that evaluations of a brand are based on multiple attributes that vary in importance. Thus, one's brand choice is related to his overall evaluation which is determined by aggregating individual evaluations adjusted for differences in importance.

This research effort utilizes four versions of the summated model and the lexicographic model as described below:

1. Unweighted summative model I (full version) -- subject's ratings on ten attributes are added.
2. Unweighted summative model II (partial version) -- subject's ratings on the five most important attributes are added.
3. Weighted summative model I (full version) -- subject's ratings on ten attributes are weighted by importance values and summed.
4. Weighted summative model II (partial version) -- subject's ratings on the five most important attributes are weighted again by importance ratings and summed.
5. Lexicographic model -- a sorting procedure in which the attributes are ranked according to importance, and alternative brands evaluated sequentially starting with the single most important attribute downward. If a tie arises, successive dimensions are used. The sorting process continues until a rank ordering of alternatives is completed.

This study, then, investigates how these various choice models may provide different predictive accuracy for persons with different characteristics and familiarity with products. Specifically, the major research objectives are to test the following hypotheses:

- H₁: The predictive accuracy of selected choice models differs between cognitively complex and cognitively simple persons.
- H₂: The predictive accuracy of selected choice models differs between persons with different levels of product familiarity.

Research Methods

Product Selection

Three products were required to differ in importance and to have multiple brands or options that were generally known to the respondents. Automobiles, rental apartments and toilet soaps were shown to meet the above criteria using a group of respondents similar to the final sample.

Research Instruments

Respondents indicated brand knowledge by the percentage of brands checked on a list of brands provided for the purpose. A person's familiarity with a product class was measured as the proportion of brands in the product class that one knew something about.

A new research approach was adopted to operationalize the choice models. Instead of imposing a standard set of attributes (dimensions) for evaluation of brands, each respondent was asked to provide his/her own attributes. Such a procedure should partially eliminate the problem of non-salient attributes. The brands (stimuli) to be evaluated were also self-selected from the larger list of brands. Arbitrary responses to unknown brands were thereby avoided.

Kelly's Repertory grid (Kelly 1955) was used to organize attributes and then to rate brands. In essence, it is a matrix which captures a person's repertoire of self-generated dimensions used in the evaluation of objects. Table 1 shows such a grid.

Cognitive complexity is computed using the matching of dimensions procedure as proposed by Bieri and colleagues

(1966). In brief, a cognitively simple person, when using the grid, would not be able to use many of the dimensions in a differentiated manner, and hence would evaluate the objects identically. The ratings in the grid are compared with one another for agreement on objects to determine the number of identical ratings. Every dimension is compared with all others. In such a manner, the entire repertoire of dimensions is examined to determine one's relative complexity. A simple person will have a high number of matches (similar to identical semantic differential profiles). A low score therefore denotes a more differentiated structure and cognitively more complex. Table 2 summarizes the results of this procedure using the data from Table 1.

Data Collection

Respondents were upperclass undergraduate students and each was paid two dollars for participation. Ninety-six persons formed the final sample. They were arranged in small group settings and detailed instructions were presented verbally and in writing with special care taken to explain the Repertory Grid routines. A repeated measure design was used in that each subject provided evaluations for all three product classes. Product presentation in the questionnaire booklets was randomly distributed to prevent order effects. Three Repertory Grids were included in each booklet.

The grid was a 10 X 10 matrix. Each respondent was instructed to pick the ten most familiar brands from a list of twenty-two and to write the brand names at the column headings. Starting from row one to row ten, the respondent was to list ten different attributes/dimensions he or she commonly used to evaluate brands of that product. Each dimension was then to be used with a six-point Likert type bipolar scale having values of +3, +2, +1, -1, -2, -3 to rate all ten brands on the grid. To assist in the generation of dimensions, three randomly pre-selected cells were circled on each row of the grid. The subject was told to look at the three brands and to consider a way, dimension, or characteristic for which two of them were similar and yet different from the third. Each dimension generated was written down on the side of the row and the procedure continued until ten bipolar dimensions were elicited. (See Kelly 1955, and Bieri et al. 1966 for details on the procedures).

In addition, preference rankings for the ten brands and importance rankings for the ten self-generated dimensions were collected. The sequence of tasks was identical for each product class.

Analyses and Results

Each subject's rank ordered brand choice prediction was derived for each model and correlated with the independently obtained preference ranking. The Spearman Rank Order Correlation was used as a measure of the accuracy of prediction of the models. In other words, the "goodness of fit" criterion was used to compare predictive ability of competing models. These correlation coefficients were then used as the dependent variables in the various analysis of variance studies.

For each product class, frequency distributions of the subjects' cognitive complexity scores and product familiarity indices were determined. The distributions were then dichotomized into the high (upper) and low (lower) halves for analyses. The final ANOVA model for each product class is a 2 X 2 X 5 repeated measure design with two fixed factors (2 levels of cognitive complexity and 2 levels of product familiarity) and one repeated factor (5 levels, one for each choice model).

TABLE 1
A Completed Rep Grid for Automobiles

Brand	1	2	3	4	5	6	7	8	9	10	
	Nova	VW Beetle	Impala	Torino	Dodge Dart	Pinto	Corvette	Mustang	LaSabre	Skylark	
<u>Dimension Positive Pole</u>											<u>Negative Pole</u>
1. Not expensive	+2	+2	+1	-1	+1	+3	-3	+1	-3	+2	Too expensive
2. Nice body shape	+1	-3	+2	+3	+2	-2	-1	+3	+1	+2	Ugly shape
3. Good gas mileage	+3	+3	+1	+1	+2	+2	-3	+2	-3	+2	Bad gas mileage
4. Lots of space	+1	-3	+3	+2	+2	-2	-2	+2	+3	+2	Little space
5. Compact in size	+2	+3	-1	-1	-1	+3	+2	+1	-3	+1	Too big
6. Smooth ride	+2	-3	+2	+2	+2	+1	+1	+1	+2	+2	Rough ride

8. Dependable	+2	-2	+2	+2	+2	-2	-3	+1	+3	+2	Not dependable
9. Engine starts easy	-1	-2	+2	+2	+2	-2	-1	+1	+3	+2	Hard to start
10. Safe	+1	-3	+3	+2	+2	-1	-3	+2	+3	+2	Unsafe

TABLE 2
Computation of Cognitive Complexity Score From the Completed Grid

Matching Scores

1-2 1, 2-3 2, 3-4 3, 4-5 0, 5-6 2, 6-7 5, 7-8 6, 8-9 8, 9-10 4,
1-3 4, 2-4 5, 3-5 2, 4-6 4, 5-7 2, 6-8 5, 7-9 5, 8-10 5,
1-4 1, 2-5 0, 3-6 2, 4-7 4, 5-8 2, 6-9 5, 7-10 4,
1-5 5, 2-6 4, 3-7 2, 4-8 5, 5-9 1, 6-10 4,
1-6 3, 2-7 4, 3-8 3, 4-9 5, 5-10 0,
1-7 2, 2-8 4, 3-9 2, 4-10 8,
1-8 4, 2-9 5, 3-10 4,
1-9 2, 2-10 4,
1-10 2,

Note: Matching scores were computed by comparing each dimension in the grid with all possible dimensions. When comparing dimension 1 with dimension 2, the number of identical ratings was one, hence a matching score of 1. The number of matches between dimension 1 and dimension 3 was four, between dimension 1 and dimension 4 was one, and so forth. The larger the matching score between two dimensions, the greater the similarity in ratings between them. Cognitive complexity score is the summation of all the matching scores. In this case, it is 154.

Table 3 summarizes the main and interaction effect significance tests for each product class. Mean scores are shown in Table 4.

Product Familiarity

Product familiarity as defined herein was not a statistically significant main effect. The overall group means for the high and low familiarity subjects are rather close. However, the high familiarity group consistently shows slightly higher mean scores than the low familiarity group across all three product classes. No further individual comparison is performed.

²p = .05

Cognitive Complexity

It was previously proposed that the predictive accuracy of selected choice models differs between cognitively complex and cognitively simple persons. And, the ANOVA results shown in Table 3 indicate significant complexity main effects for two of the three product classes. Since familiarity with product class was nonsignificant for all three products, this main effect was eliminated for presentation in Table 4.

The significance tests on cognitive complexity can be seen more clearly from Table 4 where overall mean differences for automobiles and apartments are shown to be statistically significant at 0.01 and 0.05 levels, respectively. These individual comparisons highlight differences among the five models and explain the significant main effect shown in Table 3. In the two product classes where the complexity factor is significant, four out of five individual comparisons are significant as well. All of the comparisons for toilet soaps are insignificant.

Choice Models

All three product classes show significant main effects on choice models (Table 3). This issue has been considered by many researchers and evidence of variability in predictive accuracy of different models has been well documented (Wilkie and Pessemier 1973). In general (Table 4), the weighted summative models (3 and 4) provide higher correlations than the unweighted models, (1 and 2) the full version models (1 and 3) show higher correlations than the partial version models (2 and 4), and the summative models (1 through 4) give more accurate results than the lexicographic model.

Interactions

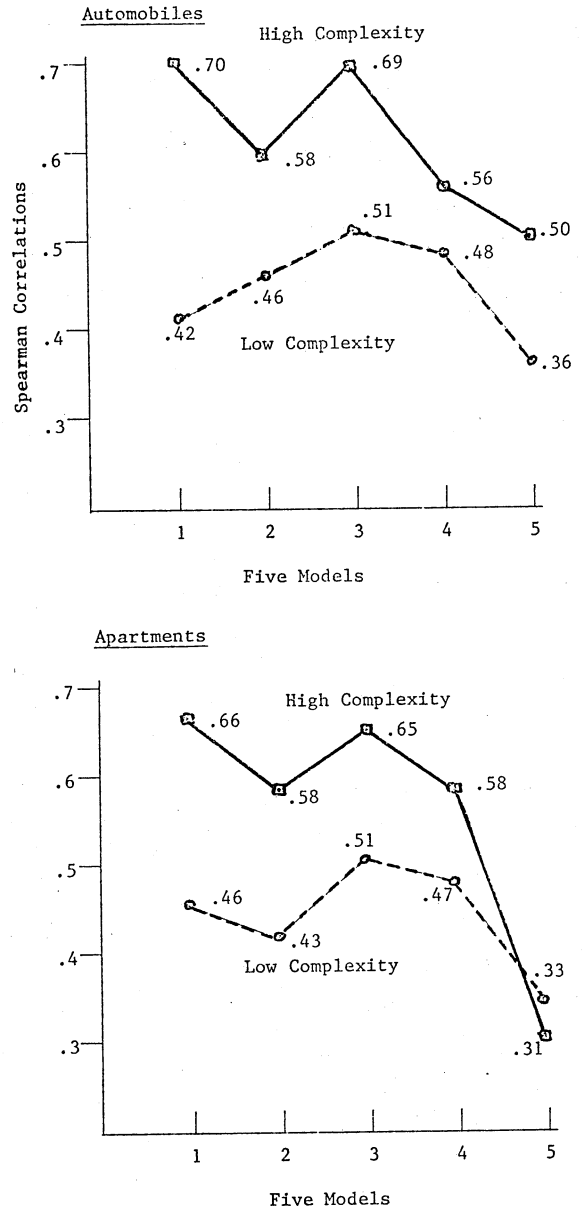

Of the various interactions, the one that shows up well is between type of model and level of complexity. Both automobiles and apartments show significant interactions. In addition, the three-way interaction is significant for the automobiles. These model-complexity interactions are presented graphically in Figure One. As can be seen, the high and low complexity subjects do not provide similar results across the five models.

Discussion

The present study found respondents differing in cognitive complexity to provide differences in accuracy of prediction for five choice models. The cognitively complex subjects appear to have consistently better predictions than the simple subjects, irrespective of the types of choice model considered. This may be due to the complex persons' more differentiated cognitions which enable them to see things in a more multi-dimensional fashion. For them, the more refined and differentiated evaluations of brands (full models) resulted in choice rankings which corresponded closely to actual preferences. Conversely, cognitively simple persons may lack the ability to see differences in brands. Brand choice predictions based on the evaluation of such dimensions may not realistically reflect actual preferences for this latter group.

For the cognitively simple subjects, the weighted summative models consistently out-perform the others. In the case of the cognitively complex subjects, the unweighted model appears to be the best predictor. In general, the differences between the full and the partial models appear to be more substantial for the cognitively complex subjects. One explanation may be that the additional attributes are meaningless to the cognitively simple subjects due to their simplistic cognitive processes, whereas, more attributes enable the cognitively complex subjects to further differentiate and thus, predict more accurately.

FIGURE 1
Model X Complexity Interaction

Cognitive complexity as a moderating variable is found here to be significant in the two product classes of highest importance. When the product is less important and rather simple such as toilet soap, no difference in predictive accuracy is found. In other words, the cognitively simple subjects seemed to be as capable as the cognitively complex subjects in evaluating stimulus objects that are inherently simple. Of the three products, the former subjects have the highest predictive accuracy in toilet soap ($r_s = 0.60$) which is significantly higher than the other two product classes ($r_s = 0.46$ and 0.43 for automobiles and apartments respectively). For the latter subjects, differences among the three products are not statistically significant ($r_s = 0.61, 0.55$ and 0.63 for automobiles, apartments and toilet soaps, respectively).

Prior familiarity with the product class was not shown to be a moderating variable in choice model predictability in this study. Persons with high and low product familiarity did not show any significant differences in the predictive accuracy of the models studied. An alternative explanation is that evaluation of brands is related more to cognitive structure than to product familiarity. Hence, a person, regardless of his/her level of brand familiarity, can still generate meaningful brand evaluations through unique cognitive capacities. Such a theoretical rationale has support. Bieri (1971) and Hall (1966) have claimed one's cognitive style to be a consistent trait manifested in different situations rather than domain specific (experience related) characteristic.

Conclusion

This research, although exploratory in nature, does provide a new perspective to a high interest area in marketing. Introducing moderating variables to the study of multi-attribute models and brand choice unveils significant details which are otherwise unnoticed.

This research is an attempt to refine our use of multi-attribute models. Of two variables with high potential as moderators, one -- cognitive complexity -- was found to be a significant factor. Persons of different levels of cognitive functioning were found to provide differences in predictive accuracy for five multi-attribute choice models.

TOWARD A COGNITIVE STRUCTURE CONCEPTUALIZATION OF PRODUCT FAMILIARITY¹

Larry J. Marks, Pennsylvania State University
Jerry C. Olson, Pennsylvania State University

Abstract

Product familiarity is conceptualized in terms of the cognitive structures of knowledge concerning the product that are stored in memory. Such knowledge could have been derived from direct or indirect experiences with the product in question (e.g., product use vs. advertisements or word-of-mouth). Different amounts and types of product experience should be reflected by variation in cognitive structure. Theoretically, differences in cognitive structures should influence the cognitive processes and outcomes that involve those cognitive structures and, thereby, should also affect overt behavior. Data from an existing study are used to illustrate these ideas. Suggestions for future research are offered.

Introduction

Concepts such as product familiarity, product experience or expertise, and/or prior information have been popular as mediating variables in many models of consumer behavior. However, despite the frequency with which product familiarity has been proposed as an individual difference variable affecting choice behavior, the concept has not yet been clearly conceptualized in a compelling manner.

The resulting confusion is apparent in the variety of terms researchers have used to describe this general concept. For example, Berelson and Steiner (1964) found that "pre-existing information" was one of several predisposing factors in determining audience receptivity to "congenial and noncongenial messages". Park (1976) measured product familiarity in terms of subjects' agreement with statements designed to operationalize Howard and Sheth's (1969) concepts of extensive, limited, and routinized problem solving. Based on the Bayesian concept of prior distribution, Woodruff (1972) used subjects' evaluations of a brand-attribute combination and their uncertainty about this rating to operationalize "prior information" about brand attributes. Lastovicka (1979) measured "knowledge about the product class" by asking subjects if they could "talk about a general group of products for a long time." He also measured "remembered personal experience" by subjects' responses to "I can remember having purchased something in this general group of products." Raju and Reilly (1979) measured product familiarity in terms of subjects' self-reported "frequency of use, overall familiarity, and knowledge of how to select the best brand." These studies exemplify the diverse and occasionally vague approaches taken in much of the past research on "familiarity." Thus far, this research has emphasized developing predictive models of consumer choice, where measures of product familiarity are one element in such models. Unfortunately, this approach has not produced a clear conceptualization of the construct of product familiarity.

The purposes of this paper are to propose a broad concep-

tualization of product familiarity, defined in terms of the cognitive structures of product knowledge that are derived from past product-related experiences, and to present initial data regarding its usefulness and validity. Our broad objectives are to begin to develop a better understanding of how product experiences are represented in cognitive structure, and of how cognitive structures influence the cognitive processes involved in handling product information (e.g., making purchase choice decisions).

Product Familiarity as Cognitive Structure

Product familiarity has often been operationalized in terms of product-related behavior, perhaps most often in terms of self-reported product usage experience or frequency of use (cf. Anderson, Engledow and Becker 1979, Jacoby, Chestnut and Fisher 1978). An information processing approach, however, provides a different perspective. From this point of view, the construct of interest is not the past product experience *per se*, but the cognitive representations of that experience that are stored in memory (see Bettman 1979, Olson 1978b, Russo and Johnson 1980). These representations can be considered to be organized in memory as a product-related cognitive structure or schema. Product schemas contain knowledge in the form of coded representations of brands, product attributes, usage situations, general product class information, as well as evaluations and choice rules. This coded information can be considered to be organized or linked together and stored in memory as a structural framework of knowledge (Norman and Bobrow 1975). Thus, product cognitive structures or schemas may contain not only factual knowledge about the product, but also evaluations or affect, and in well developed schemas, purchase criteria and even decision rules or strategies (Olson 1978a).

Given this information processing perspective, product familiarity can be defined in terms of consumers' cognitive structures for a product that were presumably caused by various product-related experiences. Consumers with different amounts or types of product-related experience probably have acquired cognitive structures with differing characteristics. These variations in cognitive structure are assumed to cause the observed behaviors previously attributed to the vague concept of "product familiarity." Specific features or characteristics of cognitive structure are addressed later.

Although this line of reasoning may be conceptually compelling, it will not have much impact on our research unless we can develop reliable and valid measures which tap, at least relatively directly, these cognitive structures for products and brands. Before addressing operational issues, however, consider the developmental aspects of product familiarity.

Effects of Product-Related Experiences on Cognitive Structure

Several authors have called for a theoretical explanation regarding how product-related experiences create cognitive structures and/or influence existing cognitive structures (cf. Olson and Mitchell 1975, Russo and Johnson 1980). Hayes-Roth (1977) presented such a conceptual framework which seems useful for considering the effects of product

¹This research was funded by a corporate grant to Peter D. Bennett, whose inputs are gratefully acknowledged along with the insightful comments of two anonymous ACR reviewers. We also thank Aydin Muderrisoglu and Robert Humberston for conducting the experimental sessions.

experience on cognitive structure (see Olson and Dover 1978). According to her model, processing information about a product creates the elementary coded representations of knowledge--the concept nodes or cogits--of a product schema. As more product-related experiences occur, these coded representations are "strengthened" in memory and associations between the knowledge nodes develop and become stronger (i.e., learning occurs). Eventually, presumably after multiple experiences with the product, the configuration of associated representations has developed to a point that it can be considered a well-developed, reasonably stable structure.

Moreover, substructures of the now "well-developed" schema may be recoded, a chunking or "unitization" process (cf. Miller 1956, Simon 1974) by which several separate components of the cognitive structure come to be treated (cognitively) as a single representation. Thus, this newly-created concept or chunk represents several other concepts. Chunking can be considered as a process of forming abstract concepts by creating more general concepts to represent several more concrete concepts. According to Hayes-Roth (1977), a chunk usually can be cognitively decomposed into its "original" components, given appropriate instructions and processing, although under ordinary circumstances it would be treated as a unitized representation.

Consumers who are quite familiar with a product due to multiple past experiences might be expected to have formed a stable, complex cognitive structure (or set of structures) of product knowledge, perhaps containing multiple chunks (Olson and Dover 1978). At least one published study provides indirect support for the chunking propositions discussed above. Edell and Mitchell (1978) found that subjects with experimentally-manipulated prior experience regarding a previously unfamiliar product category generated fewer total thoughts in response to an advertisement for a brand in that product class than did subjects with little or no prior experience. From the perspective discussed above, the experienced subjects may have generated ad-stimulated thoughts about more abstract concepts--chunks if you will, "bigger" concepts with "extra" meaning--and thus they produced fewer total responses. Certainly this interpretation is only speculative; however, as a partial test of this notion, subjects' cognitive responses could be analyzed in terms of their level of abstractness or concreteness.

Effects of Cognitive Structure on Information Processing

It is generally accepted that people use information from long-term memory to perceive, interpret, and store new information (cf. Bettman 1979, Mitchell 1978, Olson 1978b, 1980). From the perspective advocated here, product-related schemas are activated and provide the necessary cognitive structure for interpreting product information or new product experiences (see Olson 1978a). In this sense, cognitive structures have a fundamental influence on the processes of attention, encoding, evaluating, storing and using information. For instance, differences in memory schemas should be evidenced by variations in how consumers process information for which those cognitive structures are relevant, whether the information is contained in ads, for instance, or is derived from product use experiences. Thus, consumers' cognitive responses to an advertisement (Wright 1973) could provide clues about how cognitive structures influence encoding processes (Olson 1980). In sum, peoples' existing cognitive structures should exert a powerful influence on their cognitive processes and on their subsequent overt behavior.

Perhaps the major stumbling block in doing research on cognitive structures is the measurement problem. How does one measure the content and organization of a memory schema for a product? This issue is too large for a thorough discussion here. Briefly, however, Olson (1978b) has advocated "free elicitation" as a possible measurement technique. In this procedure, subjects are given cue stimuli or memory probes (usually words) and asked to "Tell me everything that comes to mind when I say..." Presumably, the verbal responses elicited in response to product and/or situation-specific probe cues can provide (admittedly imperfect) indicators of the content and perhaps the organization of cognitive structures.² In our research program thus far, we have had some success with this technique (see Kanwar, Olson and Sims 1981, Olson and Muderrisoglu 1979). A simple free elicitation procedure was used in this research to provide indices of two characteristics of a product cognitive structure.

Research Purpose

The study described below serves only as an initial, exploratory investigation of the ideas discussed above. It is exploratory because the research was designed primarily for other purposes; however, part of the original design produced data that are relevant for our objectives. Specifically, there are two broad issues of major interest. First, what differences in cognitive structures result from varying levels of product experience or familiarity? That is, do our presumed measures of cognitive structure reflect differences in product familiarity? Second, how do these cognitive structure variables affect subsequent information processing operations and the formation of product attitudes and purchase intentions?

Methods

Product and Subjects

The product was an innovative office chair. The chair had been designed to orthopedically accommodate and support the user's body in a manner that would be both healthful and comfortable. Moreover, the chair was intended to enhance the worker's task performance while working at a desk. The specific chair was totally unfamiliar to all subjects, although it was being marketed in other regions of the country. Subjects consisted of 34 business students (mostly MBA's with some senior undergrads) and 20 secretaries from the University. Subjects were volunteers selected on a convenience basis. They were paid \$4.00 for their participation.

Design

The part of the original study examined here can be represented as a simple 2 x 2 between-groups design. Two levels of product experience or familiarity (lower and higher) were represented by the student and secretary groups. The second factor was manipulated by exposing half of the subjects in each group (on a random basis) to a fairly elaborate sales promotion message for the desk chair; the remaining subjects received no product message. An after-only design was used because taking pre-exposure measures was considered to be too sensitizing, and besides, subjects

²Russo and Johnson (1980) use a thought protocol task similar to free recall tasks and the free elicitation task used here, but that may provide a somewhat different perspective on product cognitive structures.

had no pre-experimental knowledge of this particular chair that could be measured.

Product Familiarity. The main focus of interest is the cognitive structure representation of product familiarity. To maximize inferential rigor, it might have been preferable to experimentally manipulate familiarity, and thus cognitive structure. However, it is difficult to create major differences in product familiarity and related cognitive structures in the context of a controlled experiment. These variables develop naturally in the real world over relatively long periods of time and many experiences. Moreover, for the initial studies in a program of research on cognitive structure, it seemed most efficient to first establish whether differences in existing cognitive structures could be measured. Later, after we learn more about cognitive structures, we can make better attempts to manipulate them. Therefore, we chose to use the secretary and student groups as a classification variable, a surrogate "manipulation" of familiarity with office desk chairs. It seemed reasonable to assume that secretaries have greater amounts of experience and familiarity with office desk chairs than do students.

Exposure to Product Message. The second independent variable was exposure or not to a sales presentation for the new chair. Half of the subjects in each group saw a 6-minute slide show of professional quality, produced by the manufacturer, and accompanied by a synchronized tape-recorded sales presentation. In the promotion message, the product was presented as of high quality and innovative in design. Four major sales points were described verbally and portrayed visually (the chair is accommodating to one's body, health giving, task motivating, and comfortable).

Procedures

Subjects were run individually. To enhance their motivation and to provide a context for the experimental procedures, subjects were told to imagine that they were part of an employee committee at their company which was to recommend the type and style of furniture to be used in a remodeling of their offices. In fact, the chair is sometimes sold in this way. After completing an informed consent form, subjects in the exposure condition were shown the slide show presentation. Immediately after, they were asked to record "all the thoughts you had while watching the presentation." Then, concepts were elicited in response to three probe cues that were presented via the instruction, "tell me all the characteristics that come to mind when you think about buying an office desk, ... an office desk chair, ... a filing cabinet." Desk chair was always the second probe. The interviewer recorded all responses verbatim. Following the third probe, subjects rated their attitudes (A_0) and purchase intentions (BI) regarding the advertised chair.

The nonexposed subjects served as an internal control group to provide an index of peoples' normative cognitive structure regarding the three probe cues, uninfluenced by any persuasive message. After completing the informed consent form, these subjects received the free elicitation procedures. No other measures were taken (no cognitive responses, A_0 or BI).

Dependent Variables

Cognitive Structure. To measure differences in cognitive structure due to variation in product familiarity, we examined the results of the free elicitation instruction, "Tell me all the characteristics that come to mind when you think about purchasing an office desk chair." Empirical indicators of two cognitive structure characteristics were developed (see Kanwar, Olson and Sims 1981). The number of concepts elicited served as an in-

dicator of cognitive structure dimensionality and the percentage of the elicited concepts judged more "abstract" (rather than more concrete) was used as a measure of abstractness of cognitive structure.³ Whether a concept was considered abstract or concrete was based on experimenter judgment. Significant differences in these indicators were expected between the secretary and the student groups due to their presumed differences in product experience. However, exposure to the promotional message might also produce some variation.

Cognitive Processing. Immediately following the message subjects were given four minutes to write down "the thoughts they had while watching the presentation." These cognitive responses were coded in terms of the numbers of counterarguments, support arguments, and total thoughts produced. As discussed earlier, the cognitive responses of the more and less experienced groups were expected to vary because of their different product-related cognitive structures.

Attitude and Intentions. Attitude toward the chair (A_0) was measured by the mean of three bipolar, 5-point scales labeled good-bad, high quality-low quality, and like-dislike (coefficient alpha=.82). Behavioral intention (BI) was measured on a 7-point bipolar scale by asking the subjects how likely they would be to recommend purchase of the chair (not at all likely-very likely).

Results and Discussion

Check on Familiarity Classification

Intuitively, it seemed reasonable to assume that secretaries, by virtue of their daily experiences with office desk chairs, would be more familiar with the general product class than students. Thus, secretaries' cognitive structures regarding desk chairs should be different from those of students. To establish that their past experiences with desk chairs did indeed differ, we asked both secretaries and students to report several past behaviors. As expected, 100% of the secretaries had worked at a job "that involved desk work," while only 65% of the students had. Moreover, secretaries reported that 85% of their work time was spent working at a desk, compared to 67% for those students who had ever had a "desk job."

Differences in Cognitive Structure

Next, it is important to establish that the secretary-student distinction, as a surrogate "manipulation" of product familiarity, produced variation in our measures of cognitive structure. Empirically, differences between secretaries and students might be reflected in (a) the total number of salient characteristics of desks elicited, and (b) the level of abstraction of the elicited concepts. Moreover, we need to determine whether or not exposure to the persuasive sales material influenced these elicitation measures. To enhance the study's low power caused in part by the relatively small cell sizes (n 's = 17 and 10), and because the exploratory nature of this research makes us relatively more sensitive to Type II than Type I errors, we adopted an alpha level of .15 for statistical significance (cf. Cohen 1977).

³In another study, we obtained adequate levels of agreement for these two judgments between two independent coders ($r=.85$ for total number of thoughts; $r=.87$ for judgment of abstract vs. concrete; see Kanwar, Olson and Sims 1981)

⁴Two independent judges agreed on 85% of these judgments.

A 2-way, Familiarity by Exposure ANOVA showed that exposure to the sales promotion did not affect the number of concepts elicited ($p > .50$, M 's = 6.1 for exposed and 5.8 for not exposed, respectively), or the abstractness of the elicited concepts ($p > .20$, M 's = 44% and 36%). Although not statistically reliable, the modest increase in abstract concepts due to exposure was to be expected, since the sales promotion message did describe and portray several abstract ideas (regarding the comfort, healthfulness, and accommodating properties of the chair) that subjects probably were not aware of prior to message exposure. The ANOVA also revealed that the total number of elicitations for students was somewhat greater than that produced by the secretaries (M 's = 6.2 vs 5.2, $F = 6.60$, $df = 1/50$, $p = .01$). This difference is consistent with the proposition that greater product familiarity results in the chunking of cognitive elements, which in turn causes fewer verbalized responses to the elicitation probe. Implicit in this notion, however, is the requirement that those fewer, chunked concepts represent higher levels of abstraction. In fact, the presumably less familiar students did produce a lower percentage of abstract concepts than did the secretaries, but not significantly so (M 's = 41% and 34%, $p > .20$). In sum, the present data provide weak support that the surrogate "manipulation" of familiarity produced differences in cognitive structure.⁵

Effects of Cognitive Structure and Product Message

Next, we examine the effects that subjects' cognitive structures had on their responses to the promotional material. The following results are based only on those 17 students and 10 secretaries who were exposed to the sales promotion message.

Cognitive Responses. Consistent with Edell and Mitchell's (1978) results and the chunking proposition, we found that the presumably more experienced secretaries produced marginally fewer cognitive responses to the product promotion than the less experienced students (M 's = 7.0 vs 8.0, $F = 1.51$, $df = 1/26$, $p = .23$). Secretaries produced no more support arguments than students (M 's = 2.2 versus 2.0, $p > .70$), but did have fewer counterarguments (M 's = .4 versus 1.8, $F = 6.16$, $df = 1/26$, $p = .02$) than the students.

These results provide weak support for the notion that cognitive processing of a product message is influenced by one's product-related cognitive structures, which in turn reflect differences in product familiarity. By this perspective, secretaries may possess better integrated, more abstract, and presumably more effective product structures. Therefore, they might be expected to better understand and appreciate the rather complex information presented in the sales promotion message. Since the product was convincingly described as of high quality, secretaries would be expected to perceive it as such and support argue for the message, which they did, although not significantly more so than students. Moreover, secretaries would not be expected to find as many points with which to disagree in the apparently accurate product message. In contrast, students with less-well developed, product-related schemas, may not have clear criteria on which to judge the product. Thus, they might be expected to have some difficulty in relating the information in the adver-

⁵ Parenthetically, it might be noted that an office chair is not a highly complex product. Thus the degree of abstraction that logically can be expected may be somewhat limited. If so, the variance in the percentage of abstract concepts to be discovered might be rather small for a product of this type. For more complex products, differences in level of abstraction might be more apparent.

tisement to their personal experiences. If so, they would be more likely to disagree with the information and produce more counterarguments, which they in fact did. Alternatively, however, students may simply have been more cynical or critical than the secretaries, or may have felt greater "demands" to appear critical during the experimental task.

Attitude and Intentions Toward the Chair. Cognitive responses, especially counterarguments, have been shown to mediate the formation of attitudes and intentions (e.g., Olson, Toy and Dover 1978, Wright 1974). Therefore, it was expected that the secretaries would be more likely than the students to perceive the chair as being of high quality and to recommend its purchase. This was indeed the case. Secretaries had more favorable product attitudes than the students (M 's = 4.6 versus 4.1, $F = 3.03$, $df = 1/26$, $p < .10$). And, consistent with their more positive attitudes toward the chair, secretaries were more likely than students to recommend purchase of the chair (M 's = 6.0 vs 5.1, $F = 2.93$, $df = 1/26$, $p < .10$). These results lend additional credence to the presumed causal flow between cognitive responses, attitudes, and intentions (cf. Edell and Mitchell 1978, Olson, Toy and Dover 1978, Wright 1974).

Conclusions and Suggestions

Like many initial investigations of new conceptualizations and measures, the present research generates more questions than it answers. The paper's basic value is probably in raising the issue of how "product familiarity" is to be treated as a construct in consumer behavior theory. Although weak, we believe that the pattern of obtained results are sufficiently interesting to warrant further investigation.

Although the present data were derived from a larger study primarily intended to address other issues, this does not invalidate the obtained results. In particular, the elicitations were carried out about as we would do in a study specifically designed to investigate cognitive structure issues. There are, however, problems in interpreting the product familiarity/experience, student-secretary factor. Because levels of familiarity were not manipulated, a variety of other differences exist between the two groups besides their past experiences with desk chairs. These confoundings become serious if one or more of these other factors can account for the observed pattern of results.

A series of internal analyses revealed that neither age, nor sex, nor marital status could consistently account for the obtained results. A stronger rival explanation involves the experimental demand characteristics that may have been felt by the secretary subjects. Perhaps the secretaries felt that they were "expected" to react favorably to the positive information provided by the advertisement because they had job experience with the product class. While this could account for their favorable attitudes and purchase intentions, it is not clear why students would not also feel "obligated" to react favorably. Additionally, if the secretaries felt that their "expertise" was an issue, it seems likely that they would have sought other ways to demonstrate their expertise. Thus, compared to students, the secretaries should have produced more, not fewer, verbal elicitations, and more, not less, counterarguments in response to the product message. Perhaps the most compelling alternative explanation for the elicitation results is that students--especially MBA students--are rather verbal, and therefore likely to produce more concepts in a free elicitation task than secretaries. This explanation, however, cannot account for the other effects that were obtained. For instance, why should "high verbalness" have a negative effect on A_0 or BI ?

In summary, although of course it cannot be proposed with high confidence, the most parsimonious explanation for the entire range of obtained results is that members of the two groups had different cognitive structures. Interestingly, a similar study, recently published by Anderson and Jolson (1980), obtained some of the same patterns of results as found here. They found that advertisements for 35mm cameras containing relatively technical information produced more favorable beliefs and attitudes for more experienced consumers than for less experienced consumers. We would hypothesize that greater product experience produced more complex cognitive structures containing abstract concepts (chunks) and strong, clear interrelationships between concepts. Such memory schemas seem necessary in order to comprehend complex information in a meaningful way. Stated simply, complex information is more persuasive for people who are able to more fully comprehend it.

Future Research Directions

This study introduces the idea of conceptualizing product familiarity, product experience, and product expertise in terms of the cognitive structures produced by past product experience. Clearly, additional theorizing and empirical research is necessary before this conceptualization can be generally accepted for use in other research. In particular, we need a more explicit model of cognitive structure. What are the relevant characteristics of a product cognitive structure or memory schema? What measures can serve as empirical indicators of these constructs? How do these aspects of cognitive structure affect other cognitive processes such as the encoding/comprehension process or the information integration processes involved in judgment or decision making? In short, how is past experience represented in a cognitive structure? Answers to such questions will require an extensive research program focused on the construct validity of a model of cognitive structure.

We have begun such a program (cf. Olson and Dover 1978, Olson and Muderrisoglu 1979, Olson and Sims 1980) which recently has produced signs of progress (Kanwar, Olson and Sims 1981). Thus far, we have proposed three characteristics of cognitive structure: dimensionality, the number of salient concepts stored in memory, articulation, the number of discriminable categories along each dimension, and abstraction, the level of abstractness of the dimensions. In addition to free elicitations, the repertory grid procedure and a knowledge test appear to provide potential measures of these cognitive structure elements (see Kanwar, Olson and Sims 1981). These developments also indicate a need for further improvements in methodology in order to facilitate further research on cognitive structure.

The first stage of future research could use the three cognitive structure characteristics just mentioned to establish the aspects of cognitive structure that are related to varying degrees of product familiarity. It does not seem important at this time to attempt the actual manipulation of product familiarity. Rather, we should establish the differences in structure that are associated with differences in experience. Presumably, the constructs of dimensionality, articulation and abstraction vary not only across levels of familiarity, but also for types of products. If so, of course, the data patterns obtained in this preliminary research may not hold for very simple or very complex products.

Future research should attempt to replicate the present design in order to establish the generalizability of these results. For instance, differences in cognitive structures should be found between groups of subjects who

a priori have different, hopefully more extreme levels of product familiarity for several products of varying complexity. Once this step is accomplished, it is necessary to demonstrate that the measured differences in cognitive structure are related to differences in information processing behavior, to attitudes and behavioral intentions, and to overt behavior. While experimental simulations are useful for much of this research, actual field observations in a natural environment will be necessary to establish external validity.

Finally, research should focus on the developmental aspects of product familiarity created by product experience or consumer socialization or consumer education. Essentially, in a longitudinal study, subgroups of subjects could be brought to various levels of product familiarity through product experience. Both cognitive and behavior measures, which presumably would possess known reliabilities and validities by this time, should reflect the levels of product familiarity.

In sum, a wide variety of interesting questions regarding the cognitive structure representation of product familiarity can be addressed, once we have suitable criterion measures. Of course, these questions have not been answered by the present research. We have merely introduced the idea of conceptualizing product experience and product familiarity in terms of cognitive structure and have produced some data that point to the potential usefulness of this point of view. We hope that others will become interested in developing these concepts and measurement procedures further.

PRODUCT FAMILIARITY AND LEARNING NEW INFORMATION¹

Eric J. Johnson, Carnegie-Mellon University
J. Edward Russo, University of Chicago

Abstract

What is the relationship between product familiarity and the ability to learn new product information? An experiment shows that product familiarity can lead to increased learning during subsequent purchase decisions. However, this ability strongly interacts with the specific decision task: the monotonic relationship between familiarity and learning holds for judgment but not for choice. The results also show that judgment and choice strategies leave different information in memory. We believe that phased choice strategies account for this difference.

will then be brand-based or attribute-based. Examples of the interaction between inferential level and inferential basis are found in the cells of Figure 1.

Figure 1
A Taxonomy of Product Knowledge

Introduction

Product familiarity is an important factor in explaining consumer behavior. Its rule is recognized in both traditional theories (Howard and Sheth 1969, Hansen 1972, Howard 1977) and newer information processing approaches (Bettman 1979, Olson 1978). Familiarity has also received recent attention in empirical research (Olson 1979, Bettman and Park 1980a). With the exception of Bettman and Park's paper, however, little research explores the effect of familiarity on consumer information processing. The present paper reports an empirical investigation of the effect of familiarity on one important consumer behavior, learning new product information during purchase decisions.

Consumer Knowledge

In this paper, product familiarity refers to prior knowledge of the brands within a product category. Obviously, all consumers start as novices at some point before their first purchase in a product class. As the consumer gains experience, product familiarity grows, and this knowledge affects the acquisition of new product knowledge. To understand this relation between familiarity and learning, a theory of product knowledge is essential. We use a taxonomy of knowledge developed by Russo and Johnson (1980).

The two central components of this taxonomy are shown in Figure 1. The level of inference refers to the relationship between external information and knowledge in memory. This resembles a hierarchy. New knowledge starts with externally available information, the brand-attribute values at Level 5 in Figure 1. The purchase decision process generates additional intermediate knowledge in the natural course of comparisons among brands. Finally, there is knowledge of the best brand, shown as Level 1 at the top of the hierarchy.

Knowledge can also be classified by its inferential basis, the dimension across the top of Figure 1. Consumers can make decisions using either brand-based or attribute-based strategies (Bettman 1979). The resultant product knowledge

INFERENTIAL LEVEL	INFERENTIAL BASIS	
	ATTRIBUTE	BRAND
1. Best Brand		"My favorite is Excedrin."
2. Whole Comparisons	"The main thing most people think about ... is the cost of gas."	"I've always wanted a Cadillac, much more so than a Lincoln."
3. Whole Evaluations	"I never worry about calories in any product."	"Liver is excellent."
4. Single Comparisons	"The next cheapest, I think, would be tuna."	"The best thing about chicken is its price."
5. Single Evaluations	"Beef liver is another very economical food."	

With this scheme for characterizing product knowledge, both old and newly acquired, we can ask how product familiarity affects learning additional product information. There are two plausible hypotheses.

The first, which might be called the "enrichment hypothesis", derives from cognitive psychology. It has been repeatedly demonstrated that greater prior knowledge facilitates learning. One classic example is the research on chess performed by Chase and Simon (1973). They showed a number of board positions to both chess masters and novice players for five seconds apiece. Knowledgeable subjects remembered much more than novices. However, when shown random patterns of chess pieces, the masters' recall was no

¹ The authors thank Jim Bettman for his comments on an earlier draft. The first author is now at the Department of Psychology, Stanford University, Stanford, CA 94305. This work was supported by National Science Foundation Grant #DAR76-81806 to the second author.

better than the novices'. This, Chase and Simon argued, was because the recall of random positions did not use the superior knowledge of the chess masters. Thus, the "enrichment hypothesis" argues that prior knowledge provides experienced consumers with better encoding and recall skills. Therefore, when confronted with new information, greater experience facilitates greater learning, a "rich get richer" hypothesis. This pattern would generate data similar to the exponential curve in Figure 2.

Figure 2
Alternative Hypothetical Relations
Between Product Familiarity and Learning

In contrast, Bettman and Park (1980a) claim that prior knowledge has the "inverted U" effect shown in Figure 2. They are concerned with external information search, but it seems natural to extend their hypothesis to the knowledge that remains in memory after search. In their view, very inexperienced consumers have difficulty understanding new information, and therefore search less. Consumers with a moderate level of knowledge search widely; they can both understand the new information and also benefit from its retention in memory. Finally, very experienced consumers search less. Although they can understand new product information, they have little need of it. This hypothesis was confirmed by Bettman and Park's search data, and the same "inverted U" effect might describe newly acquired knowledge in memory.

Experimental Rationale

To test these two hypotheses, we performed an experiment that used a brand-by-attribute display of information. The matrix contained new information about sub-compact cars that had just become available at the beginning of the model year. Consumer subjects, differing in their familiarity with automobiles, were instructed to evaluate the cars using only this information. A surprise recall of this information provided us with evidence of the role of prior knowledge in learning (remembering) new product knowledge.

Choice Versus Judgment

Besides the effect of different levels of familiarity, we added a second manipulation. We suspected that the strategy used to evaluate products would influence the product knowledge that was acquired and, therefore, remembered. First, consider a conventional choice task, i.e. choosing the best of several alternatives. Bettman and Park (1980b), Wright and Barbour (1977), and Johnson and Russo (1978) all find clear support for the use of phased decision rules in consumer choice. If subjects used phased strategies, some alternatives should be eliminated quickly, on the basis of only one or two pieces of information. Less knowledge of these eliminated brands should be generated and retained in memory. Some support for these claims was found by Johnson and Russo (1978).

In contrast with a choice task, subjects can also judge the overall quality of each alternative. This second task should force subjects to analyze, and remember, equal amounts of information for every alternative. In this experiment, half the subjects performed an ordinary preferential choice task, while the other half rated each alternative on a scale of attractiveness.

Method

Subjects

The 54 subjects participating in this experiment were students in the evening master's program of the Graduate School of Business of the University of Chicago. They completed the task as part of a classroom demonstration during the first meeting of a consumer behavior course. The product category, new sub-compact cars, was selected so this subject population would represent at least one segment of typical purchasers. Their demonstrated interest in the task partially confirmed this.

Stimulus

The brand-by-attribute matrix shown to the subjects was an edited copy of an advertisement placed by General Motors' Oldsmobile Division. Originally the advertisement compared one model of Oldsmobile to a number of imported sub-compact automobiles. By removing the Oldsmobile from the choice set, we created a matrix that had no dominant alternative, yet preserved the interrelationships among the attributes that naturally occurred in the marketplace. Additionally, we deleted anything beyond one model per manufacturer to avoid possible confusion during recall. These actions left a matrix of eight alternatives, all smaller imported cars. They were rated on ten attributes: model, transmission, engine (number of cylinders), EPA estimated miles per gallon, fuel tank capacity, estimated driving range, passenger capacity, interior volume, trunk volume, and the manufacturer's suggested retail price.

Procedure

Subjects were run in a single group. At the beginning of the session, they were given a booklet containing all experimental materials. The first page presented the appropriate task instructions and requested that they not proceed until asked to do so by the experimenter.

Judgment Task. In the judgment condition, the instructions informed the subjects that they would be given a brand-by-attribute matrix of information relevant to automobiles. They were asked to judge each of the automobiles on a seven-point scale, based only on the information provided, and not prior knowledge.

Choice Task. Subjects in the choice task were similarly informed of the brand-attribute matrix, but were asked to choose the most preferred of the eight automobiles rather than make individual judgments.

When all subjects finished their respective tasks, they were asked to turn the page to a "Demographic Questionnaire." This page had two purposes. First, it was used to gather demographic information, including a self-rating of product familiarity. Subjects were asked to "rate your previous knowledge of automobiles, compared to the rest of the population", on a five-point scale. Second, the recall of demographic facts prevented the retention of product information in short-term memory.

Subjects were then instructed to turn the page and read the instructions for the unexpected recall task. They were told to "try to recall as much as you possibly can." This included not only the information that they were given but also any "observations and judgments about the alternatives and the attributes." These instructions were designed to encourage complete recall, including information at the higher levels of inference. Subjects were then given an unlimited time to record their recall on blank sheets of paper. After the recall was completed, subjects were asked to report the car selected as best, any past experience with each of the eight automobiles, and the strategy they used to perform the choice or judgment task.

Analysis

The written protocols were divided into a series of "complete thoughts" (Newell and Simon 1972) and then coded according to the scheme shown in Figure 1 and described in Russo and Johnson (1980). This scheme is similar to the one used by Bettman and Park (1980a).

Familiarity with the product category was measured by subjects' self-reports on the scale described above. The distribution of these self-ratings was concentrated at the middle value. Self-ratings at or below 2 were classified in the low familiarity group, between 3 and 4 as the moderate familiarity group, and above 4 as the high familiarity group. The number of subjects in each familiarity condition was 12, 27 and 16, respectively.

The factor of task, judgment versus choice, was crossed with the three levels of familiarity to create a 2 X 3 factorial design (with unequal cell sizes). This two-factor design served as the basis for all analyses reported.

Results

We have claimed that the information presented to subjects represented new knowledge, even to the subjects with greater product familiarity. This was reinforced by task instructions asking subjects to limit their attention to the information presented. However, to check the validity of this claim, we examined the recall protocols for accuracy and intrusions. Inaccurate information could come from two sources: either outside knowledge or a faulty remembrance of the presented information.

A rater blind to our hypotheses, coded each brand-attribute value on a five-point scale. Inaccurate recall was defined as those statements rated 4 (somewhat inaccurate) and above, and accounted for less than 10% of the information recalled. When the numbers of intrusions and inaccuracies are included as covariates in the analyses of variance, our results remain unchanged. Thus, the results that follow are probably not due to the recall of previously remembered information by the highly familiar consumers.

Familiarity

What is the relationship between existing product knowledge and the ability to learn new information? We have considered two possible relationships: the "enrichment hypothesis" and the "inverted U" hypothesis, shown in Figure 2. A test of these two plausible relationships between familiarity and learning can be based on the total amount of knowledge recalled as a function of familiarity.

The mean number of statements recalled increases with the level of familiarity. For the low, medium and high levels, the mean frequencies were 12.0, 16.6 and 21.1, respectively. However, an analysis of variance shows that this effect is only marginally significant ($F(2,49) = 2.825, p < .07$). Nonetheless, the pattern of results mildly supports the "enrichment" hypothesis: increased familiarity does lead to the recall of more new information.

A closer look at these data reveals that the effect of familiarity interacts with the evaluation task. The mean number of statements recalled is plotted separately for choice and judgment tasks in Figure 3. For judgment, the enrichment effect is large and consistent, with highly familiar consumers recalling two and one-half times as much information as the low familiarity consumers (28.6 versus 11.6 statements per protocol). The consumers who were asked to choose one brand, however, show an "inverted U" relationship. The subjects moderately familiar with automobiles exhibit the greatest recall. The ANOVA shows that this familiarity by task interaction is reliable, $F(2,49) = 3.20, p < .05$. A priori contrasts indicate that the judgment condition contains a significant linear relationship with familiarity, ($F(1,49) = 8.32, p < .001$). In contrast, the group making choices exhibits the inverted U or quadratic relationship ($F(1,49) = 4.11, p < .06$).

Figure 3
Learning as a Function of Familiarity and Task

Thus, while the enrichment hypothesis holds for consumers making judgments, it does not describe the memory of consumers making choices. As Bettman and Park predict, moderately familiar consumers search and remember more information.

Choice versus Judgment

How do these decision strategies affect newly acquired product knowledge? An important manipulation in this study concerns the task instructions. The consumers either chose one alternative or judged the overall quality of each alternative. We suspect that these two tasks require different patterns of information processing.

If, as we believe, consumers use phased choice rules, they first examine the alternatives in an attribute-based manner, using this information to eliminate alternatives. Eventually, the basis of the decision process shifts, and

the remaining alternatives are examined more intensively. This later processing is by brand (Bettman and Park 1980b, Bettman 1979, Johnson and Russo 1978). As a consequence of this phased strategy, more information is examined and recalled for the chosen alternatives (Payne 1976, Johnson and Russo 1978). This differential recall is also affected by the level of inference (Russo and Johnson 1980). If a brand is eliminated early in the choice process, few higher level inferences should be made. Thus, the higher the inferential level, the greater the recall advantage of the chosen brand (Johnson and Russo 1978).

In contrast, the judgment task does not permit the use of phased strategies. Because subjects rated all eight automobiles, they were required to examine information for every alternative. Thus, in the judgment task we expect equal recall for all brands, preferred or not.

To test these predictions, we tallied the number of statements in each protocol that referred to the automobile selected by the subject. In the choice condition, this was the most preferred alternative. In judgment, subjects reported which car they judged as the best. The proportion of recalled statements referring to the preferred automobile is .35 for the choice task and .18 for judgment. This difference was highly significant ($F(1,49) = 13.84, p < .001$). In addition, both values, including the 18% observed in the judgment task, are significantly greater than the 12.5% expected by chance ($p < .001$). These data provide clear evidence of the use of phased strategies in the choice task, and identify much smaller effects for judgment instructions.

To further examine memory for chosen products, we broke down the proportions of statements referring to chosen products by task and level of familiarity. The means are shown in Table 1.

Table 1
Proportion of Statements Referring to
the Preferred Alternative

<u>Low</u> <u>Familiarity</u>	<u>Moderate</u> <u>Familiarity</u>	<u>High</u> <u>Familiarity</u>	<u>Mean</u>
<u>Choice Task Instructions</u>			
.32	.27	.54	.35
<u>Judgment Task Instructions</u>			
.13	.23	.12	.18
<u>Mean</u>			
.24	.25	.36	.27

An ANOVA confirms that there is a task-by-level interaction. For judgment there is no effect of familiarity, but the choice task shows a large effect ($F(2,49) = 5.82, p < .01$). Half the recall of high familiarity subjects in the choice condition referred to the car they chose. This compares to less than a third for the low and moderate familiarity groups. A priori comparisons confirm the reliability of this pattern ($F(1,49) = 11.20, p < .005$).

Overall, the data indicate that the consumers who made choices used phased rules which eliminate alternatives, while consumers making judgments did not. Familiarity leads

to an increasingly selective memory for information about the chosen product caused, we suspect, by the use of highly selective search. The most experienced consumers do not look at all the new information, only that which they consider useful.

Types of Product Knowledge

Let us return to the taxonomy of product knowledge discussed earlier and summarized in Figure 1. Do the above results hold over all levels of inference? To answer this question the recalled statements were partitioned into five inferential levels. The same two-factor (familiarity and task) ANOVA was performed on the number of statements at each level. The only differences attributable to the main effect of familiarity occurred at Level 5, brand-attribute values, ($F(2,49) = 3.46, p < .05$). This lowest level of product knowledge consists simply of the values in the brand-by-attribute matrix. This is also the only inferential level that shows a significant familiarity-by-task interaction ($F(2,49) = 3.65, p < .05$). Thus, differences in recall can be attributed entirely to knowledge at the lowest level of processing, the acquisition of the presented brand-attribute values. No other inferential level shows these effects.

How Does Familiarity Work?

Can these results help explain the differential effects of familiarity on choice and judgment? Recall that Bettman and Park explain their "inverted U" results by claiming that experienced consumers use internal search as a substitute for external search. Because of our earlier analysis of intrusions into recall, we suspect that experienced subjects did not use stored knowledge of the brand-attribute values. Since little of the information recalled deviates from the information presented (less than 10%), internal search of existing knowledge was probably not a factor. Thus, we need another explanation for these results.

An alternate explanation of increased familiarity relies on other aspects of experienced consumers' prior knowledge. There is little doubt that experienced consumers have a great deal of information about products stored in memory (Russo and Johnson 1980). This knowledge contains more than just facts about the relations among competing brands. In addition, experienced consumers learn which attributes are most important, and should subsequently focus on these attributes in making a choice. This is a type of higher-level knowledge that goes beyond particular brands. It implies that, with experience, consumers become more selective in their search for information, and use more narrowly focused phased decision rules.

We did not collect decision protocols in this study. This means we cannot examine the decision processes directly. But we did find that differences in memory for chosen and rejected products will be greater for more experienced consumers resulting from their more selective search. This was demonstrated by the significant familiarity-by-task interaction displayed in Table 1. Also, as we have already seen, the effect of familiarity is confined to the earliest, low-level inferences. These inferences come from the initial examination of the matrix which, according to this model, experienced consumers delete from their decision processes.

Is one explanation of familiarity effects superior to the other? We cannot provide a definitive answer with these data. Our "knowledge of the attributes" explanation is very similar Bettman and Park's, and differs only for information previously unseen by the consumer. But in the real world, both mechanisms probably operate, and increase the effects of familiarity. A knowledge of important attributes, along with a knowledge of brand-specific facts, can limit the search of experienced consumers. So for many real world situations, differences in the explanations may not matter.

The unique contribution of the current explanation is limited to new information, whether from new products, or new product classes.

Discussion

What does all this mean for the study of consumer behavior? It is important to see where the present results fit in the growing literature on consumer information processing. A surprisingly consonant view of consumer information processing is emerging from a number of investigators working within different experimental paradigms, and with different products and subject populations. First, recent work calls attention to the predominance of phased strategies in choice (Bettman and Park 1980b, Wright and Barbour 1977, Payne 1976). More work is needed in display formats other than the brand-by-attribute matrix. However, we now know that phased strategies affect not only information acquisition, but also subsequent memory. Second, familiarity with product classes has an effect on decision and search behavior. At first, it leads to an increase in external search and subsequent recall. But with high levels of familiarity, both information search and memory for new information decline (Bettman and Park 1980b).

This paper attempts to make two additional contributions to this area. First, we try to extend the concepts advanced by Bettman and Park to memory for new product information. Second, we offer an alternative explanation for why experienced consumers search less information. We argue that this is not caused by the presence of relevant information stored in memory, but by their higher-level knowledge of the product class and its important attributes. They search less information and use more selective, phased decision rules that delete the preliminary exploration of external information.

These findings have implications for public and private providers of product information. They suggest that information use will be segmented by the familiarity level of the consumer. The most important implication is that providing a brand-by-attribute matrix for a low familiarity segment may do little good. Simply posting information is probably ineffectual, especially for technically sophisticated products and attributes. To help these consumers make better decisions, information about the attributes, their importance, and their relationship to quality must be provided.

PRODUCT FAMILIARITY: CRITICAL COMMENTS ON SELECTED
STUDIES AND THEORETICAL EXTENSIONS

M. Joseph Sirgy, Virginia Polytechnic Institute and State University

Abstract

This paper addresses a number of conceptual and methodological issues involving product familiarity. First, some of the general conceptualization and measurement problems were discussed. Second, the studies of Marks and Olson (1981), Tan and Dolich (1981), and Johnson and Russo (1981) were criticized for their weaknesses. Third, an eclectic cognitive view of product familiarity was introduced. And finally, recommendations for future research involving product familiarity were suggested.

Introduction

Product familiarity seems to be an emerging variable in the study of consumer behavior. Consumer researchers have used it to explain a number of consumer-related phenomena such as, message acceptance (e.g., Marks & Olson 1981), choice of decision rule (e.g. Parks 1976, Tan & Dolich 1981), product preference and purchase intention (e.g., Marks & Olson 1981), product satisfaction (e.g., Anderson, Engledow & Becker 1979), and new learning (Johnson & Russo 1981). Overall, the pattern of results utilizing product familiarity as an explanatory variable seems conflicting. The primary cause of this lack of clarity of the precise role of product familiarity as a determinant of consumer behavior may be due to the ambiguity displayed in the conceptualization and measurement of product familiarity.

This discussion will (1) focus on some of the conceptualization and measurement efforts revealed in the consumer behavior literature, (2) criticize the studies of Marks and Olson (1981), Tan and Dolich, (1981), and Johnson and Russo, (1981), which treat product familiarity as an explanatory variable of consumer behavior phenomena, (3) provide an eclectic cognitive view of product familiarity, and (4) suggest recommendations for future research in relation to product familiarity.

Conceptualization and Operationalization of Product Familiarity

One important issue concerning the conceptualization and measurement efforts of product familiarity is the unidimensional versus multidimensional treatment of product familiarity.

Product familiarity has been conceptualized and operationalized differently by different investigators. In the unidimensional tradition, Park (1976) measured product familiarity in terms of subjects' agreement with statements about the product. Woodruff (1972) used a free-recall method of purchase situations. Raju and Reilly (1979) employed self-reported "frequency of use, overall familiarity, and knowledge of how to select best brand" as measures of product familiarity. Anderson, Engledow, and Becker (1979) and Jacoby, Chestnut, and Fisher (1978) used a frequency of purchase measure as an indicator of product familiarity. Johnson and Russo (1981) used a global self-report rating measure - subjects were asked to rate their previous knowledge of automobiles compared to the rest of the population. Tan and Dolich (1981) measured product familiarity by the proportion of brands in the product class that one knew something about.

The main problem with these measures is that they are atheoretical. That is, they are not based on any one theory. In contrast, the multidimensional measurement of product familiarity, as established by Olson and his associates (e.g., Marks & Olson 1981, Kanwar, Olson, & Sims 1981, Olson & Muderrisoglu 1979), is based on the cognitive theory involving cognitive structures. The dimensions that Olson and his associates worked with are: (1) dimensionality which is defined as the number of activatable concepts associated with a particular domain, (2) articulation defined as the number of category representations or levels for each salient dimension in memory, and (3) abstraction defined as the degree to which salient, activatable dimensions are abstract versus concrete. Although more than three dimensions were identified as constituting product familiarity (reference was scantily made to the interrelatedness and centrality dimensions), Marks and Olson (1981) conceptually treated product familiarity only along the dimensionality and abstractness dimensions. High product familiarity was viewed to reflect high abstractness and low dimensionality and vice versa.

There are a number of problems which marks Olson's conceptual treatment of product familiarity. First, it is not clear how the dimensionality of product familiarity is different from its articulation. It seems to me that articulation denotes (or should I say connotes) the extent to which a psychological concept is encoded as symbolic or semantic. Symbolic psychological concepts can be construed as less articulated and semantic concepts as being more articulated. Also, how does dimensionality differ from interrelatedness? Furthermore, why wasn't the dimension of centrality incorporated in the main product familiarity schema? And finally but most importantly, why wasn't the certainty dimension considered at all? To me, product familiarity taps those beliefs (or "saliency weights" using Rosenberg-Fishbein's terminology) stored in memory. The degree of certainty of beliefs is construed to be extremely important as it affects psychological processes such as alternative evaluation and attitude change (see Fishbein and Ajzen 1975).

The measurement technique which was consistently used in most of Olson's studies (e.g., Marks & Olson 1981, Kanwar, Olson & Sims 1981, Olson & Muderrisoglu 1979) is the free-elicitation technique. Kanwar, Olson, and Sims (1981) have attempted to provide construct validation to the free-elicitation measure by relating it to product familiarity scores of a Rep test and a self-report "knowledge" measure. The results did not provide clear-cut support for the construct validity of the free-elicitation measure. However, Olson and his associates have continuously used it knowing fully that the measure's construct validity is yet to be demonstrated. Even Olson's latest study (Marks and Olson 1981), which will be discussed later in some detail, failed to provide the free-elicitation measure with the desired nomological validity. It should be noted that the free-elicitation technique is not different from the psychoanalytic technique of free-association which has been used extensively in the clinical psychology literature. It was fairly well recognized by Freud himself that the free-association technique had its share of problems. Subjects' responses are contaminated by perceptual cues, social desirability factors, memory factors, and other situational influences (The Standard Edition of the Complete Psychological Works of Sigmund Freud, 1953-1974).

Product Familiarity as a Determinant of Consumer Behavior

Marks and Olson's (1981) study was primarily concerned with the effect of product familiarity on message acceptance, product preference, and purchase intention. Tan and Dolich's (1981) study focused on the role that product familiarity plays in the selection of decision rules. Johnson and Russo's (1981) study on the other hand, examined the role of product familiarity in new learning. Each of these studies will be scrutinized in the following sections.

Effect of Product Familiarity on Message Acceptance. Marks and Olson (1981) expected that high product familiarity would induce greater cognitive responses related to support arguments, less cognitive responses related to counterarguments, and overall fewer cognitive responses than under low product familiarity conditions. The results only showed that high product familiarity generated fewer counterarguments.

There are a number of problems in Marks and Olson's (1981) message acceptance part of the study that I can see off-hand. First, even though 2/3 of their hypotheses (although not clearly stated) were not confirmed by the results, the support provided for the relationship between product familiarity and counterarguments can be due to experimental artifacts such as, experimental demand and/or nature of the sample.

Second, I was troubled by the fact that no theoretical justification was adequately provided to support the relationship between product familiarity and message acceptance in this allegedly important study in which a theory for product familiarity is advocated.

Third, one needs to realize that counterargument, among other cognitive responses such as source derogation, is a cognitive response mode designed to protect an interrelationship of existing psychological concepts. Each psychological concept has a value and a belief dimension. The belief dimension is that dimension which links one psychological concept to another (cf. Fishbein & Ajzen 1975). Product familiarity is generally represented as belief dimensions. Now, concerning the psychological dynamics involved in support and counterarguments, the following explanation is in order. A cognitive response is usually activated by a cognitive comparison between a perceptual set and an internally evoked cognitive set. Incongruence between the two sets usually leads to counterargumentation, source derogation, among other cognitive responses. This serves to protect the existing cognitive set from the threat of change inflicted by the perceptual set. Congruence between the two sets, on the other hand, generally leads to support argumentation among other responses and therefore serves to strengthen the existing cognitive set (Sirgy, in press a, in press b, Wright 1973). Based on this theoretical perspective, what would be the role of product familiarity in support or counterarguments? Product evaluation (or existing attitude toward the product) is the major determinant of support or counterargument. Product familiarity is just one component of product evaluation. Viewed from Rosenberg-Fishbein's multi-attribute attitude model, product familiarity reflects the set of saliency weights, whereas product evaluation represents the overall attitude.

Effect of Product Familiarity on Product Preference and Purchase Intention. Marks and Olson (1981) argued that since counterargument is expected to affect attitudes, subjects who are more familiar with the product (i.e., secretaries) would be more likely than those who are less familiar with the product (i.e., students) to recommend its purchase. Although the results were consistent with the hypothesis, it can be argued that the effect could have been due to an artifact of the sample and/or

experimental demands not to mention the equivocal measurement of product familiarity. Theoretically speaking, product familiarity does not independently or directly affect product preference and purchase intention but interacts with values which, in turn, interacts with perceptual elements to determine change in attitude and therefore behavior.

Effect of Product Familiarity on Decision Rule Selection. Tan and Dolich (1981) used product familiarity along with cognitive complexity to determine their effect on the use of decision rules in consumer behavior. The results indicated that product familiarity plays a negligible role in the selection of decision rules in consumer behavior, and that cognitive complexity plays a significant role. These results are extremely interesting however not totally convincing.

First, no theoretical justification was provided for the choice of the designated decision rules in the study. One may argue that product familiarity would have played a major role in the selection of other types of decision rules such as, the maximax rule compared to the minimax or maximin rules (see Edwards & Tversky 1967, Fishburn 1964, Kaufman 1968, Raiffa 1968, White 1969).

Second, the measurement of product familiarity "through the proportion of brands in the product class that one knew something about" could be a very misleading indicator of product familiarity. It is quite conceivable that a consumer could be highly familiar with one or two brands while knowing little about other competing brands.

Third, attractiveness values were used without any differentiation between its individual components (i.e., salience weights, importance weights, evaluative weights, and determinance weights). Knowing something about, for example, salience weights, can provide us with further insights concerning the dynamics involved in decision rule selection. To exemplify, it is possible that those attributes which are highly salient are included in the final decision and therefore reflecting the usage of a partial version of the compensatory model. Also importance weights (which can be construed as a dimension of product familiarity) may have a lot to do with decision rule selection. Attributes which are more important than others may lead to the adoption of a partial compensatory model which only includes those important attributes.

Effect of Product Familiarity on New Learning. Johnson and Russo (1981) examined the interaction of product familiarity and type of decision rule (attribute versus brand strategy) on learning of new information. The results provided support for the role of the "enrichment hypothesis." That is, product familiarity facilitates new learning. However, this main effect was qualified by an interaction effect between product familiarity and type of decision rule on learning of new information, and therefore providing some support for the "inverted-U hypothesis." That is, use of attribute strategy accompanied by high product familiarity contributed to new learning more than with the use of brand strategy.

Again, these results are very intriguing but not terribly convincing. This may be due to a number of problems: First, the enrichment hypothesis refers to the enhancing effect of internal existing information stored in memory on new learning (Chase & Simon 1973), whereas the inverted-U hypothesis refers to the enhancing or inhibiting effects of external information on new learning (see Jacoby, Speller & Kohn 1974, Jacoby, Speller & Berning 1974). Consequently, these two hypothesis should not be construed as competing since they operate at different levels.

Second, since the inverted-U hypothesis refers to the effect of amount of external information on learning, it

seems to me that it should have little to do with the type of decision strategy (attribute versus brand strategy) as a suitable operationalization of the principle. A more suitable operationalization of the inverted-U hypothesis would involve amount of external information as opposed to type of decision strategy.

Third, subjects were specifically instructed to make a decision by rating each automobile. They weren't specifically asked to learn the material. The surprise recall measure cannot be treated as a reliable and valid measure of new learning. New learning under these conditions can be severely affected by the nature of the task, personality and motivational factors, and other situational influences.

Fourth, subjects were asked to rate each of the seven automobiles based on the information provided, and not prior knowledge. It seems to me that it would be quite difficult for a subject to ignore previous information by simply asking him/her to do so. It is therefore very likely that previous information was indeed a confounding variable which was not adequately controlled for.

Fifth, in the judgment task, it was assumed that by judging each automobile separately, subjects are not making comparative judgments based on some specific other car or based on the preceding car, among other alternatives.

And last but not least, the measurement problem involving product familiarity has to be pointed out. Product familiarity was measured by instructing subjects to "rate your previous knowledge of automobiles compared to the rest of the population." Besides its atheoretical overtones, this measure of product familiarity is confounded by (1) individual differences in the interpretation of "the rest of the population." (2) social desirability factors, (3) as well as personality factors such as cognitive complexity (i.e., cognitively complex subjects may

have difficulty making global judgments compared to cognitively simple individuals), and (4) self-concepts related to mechanical devices (i.e., an individual who perceives himself as being mechanically inclined might rate his familiarity with automobiles as high despite his lack of knowledge in this area to avoid cognitive inconsistency).

An Eclectic Cognitive View of Product Familiarity

Figure 1 shows a cross-sectional and transverse view of a hypothetical physical space of cognitive structures. To fully understand product familiarity, one needs to describe how product familiarity is represented within an individual's cognitive structures. This position is quite similar to the one espoused by Olson and his associates, however, differs with respect to the delineation of cognitive structures and product familiarity dimensions.

From the cross-sectional view of cognitive structures of Figure 1, cognitions are basically represented as psychological concepts or "nodes." Each psychological concept which is content-specific is surrounded by a layer representing the value placed on that concept. The thickness of this layer reflects the positivity or negativity or direction of the value placed on that concept. Darker shades represent negative values whereas lighter shades represent positive values.

Some concepts are linked to other concepts through belief links. Each belief link is a content-specific psychological association and is directed (i.e., excitation travels in one direction). The thickness of a belief link is indicative of its degree of certainty. The thicker the belief dimension the higher the certainty projection.

Psychological concepts are also spatially arranged along a central-peripheral dimension. Central concepts are more abstract and more interrelated than peripheral concepts.

FIGURE 1

Cross Sectional View of a Hypothetical Physical Space of Cognitive Structures

Transverse View of a Hypothetical Physical Space of Cognitive Structures

Peripheral concepts can be referred to as attributes; the more central concepts as schemata and scripts.

As shown in the transverse view of cognitive structures of Figure 1, psychological concepts are also arranged along an articulation dimension. Concepts which are highly articulated are usually encoded in semantic or verbal form, whereas those which are less articulated are encoded in symbolic or nonverbal form.

This eclectic view of cognitive structures has been influenced by the writings of Kelly (1955), Rokeach (1960), and Epstein (1973), Ableson (1976), Collins and Loftus (1975), and Kosslyn and Pomerantz (1977).

Now the question arises concerning the cognitive representation of product familiarity within the space of cognitive structures. The position which is taken by this author is that product familiarity is represented by those belief dimensions connecting the psychological concept of a particular product with other psychological concepts representing the product attributes.

Those belief dimensions describing product familiarity can be characterized by at least eleven dimensions: (1) content, (2) direction, (3) certainty, (4) centrality, (5) articulation, (6) interrelatedness, (7) consistency, (8) stability, (9) accuracy, (10) verifiability, and (11) frame-of-reference.

Content of a belief dimension refers to the specific content of the association between two psychological concepts. For example, the Ford Escort automobile is an economy car. The verb "is" is a content-specific belief linking the psychological concept "Ford Escort" with "an economy car." Direction of a belief dimension refers to the flow of activation from one concept to another (see Figure 1). In the above example, the flow is from the psychological concept "Ford Escort" to "an economy car" and not necessarily vice-versa. Certainty of a belief dimension refers to the strength of the link between two concepts and is represented by the layer's thickness of a given link (see Figure 1). In the above example, the belief that Ford Escort is indeed an economy car may be of high certainty or low certainty. Centrality refers to the degree of salience, importance, or abstractness of a given concept. In this case, the product concept "Ford Escort" may be closer to the periphery than to the center (see Figure 1). Articulation refers to the extent to which a psychological concept is verbal (semantic) versus nonverbal (symbolic). The "Ford Escort" as a psychological concept may be encoded more on a verbal-semantic level than a nonverbal-symbolic level and therefore is more articulated in form. Interrelatedness refers to the number of attribute concepts which a psychological schema is linked with. A highly interrelated product concept is therefore associated with many attributes. Ford Escort may be associated with only high gas mileage in a consumer's mind, and therefore is said to have low interrelatedness. Another consumer may associate Ford Escort with high gas mileage, style, safety, reliability, roominess, and patriotism. The latter consumer's product concept is said to be highly interrelated. Consistency refers to the degree to which the attributes associated with a psychological schema are consistent with one another. For example, a consumer who knows Ford Escort is economical and stylish but also as being unsafe and unreliable is holding an inconsistent set of attributes. Whereas a consumer who thinks of Ford Escort as being economical, stylish, safe, and reliable holds a consistent set of attributes. Also, the consumer who relates the Ford Escort to being uneconomical, lacking style, being unsafe and unreliable is also holding a consistent set of attributes. Stability refers to the extent to which knowledge of a particular concept is durable across time. A person who may know something about Ford Escort today but forgets it tomorrow

lacks temporal stability. Accuracy refers to the extent to which the set of beliefs linking a psychological schema to a set of attributes are representative of the true state-of-affairs, or just simply having accurate perceptions. A consumer who thinks that the Ford Escort is a luxury uneconomical car has inaccurate product perceptions. Verifiability refers to the extent to which an individual feels that the beliefs associating a psychological schema (or product concept) with a set of attributes can be somehow verifiable. A person who believes that God controls one's destiny may feel that this kind of belief is unverifiable, however his belief that the Ford Escort is economical can be verified through actual experience. And finally, frame-of-reference refers to that psychological "script" which the individual is presently using during which certain associations between a psychological schema and its attributes become activated. For example, if one approaches the Ford Escort from a consumer's union frame-of-reference, a totally different set of attributes might be activated (e.g., safety, economy, reliability) compared to a shopper's frame-of-reference.

How does product familiarity differ from product evaluation? The only difference that I can see in these two phenomena is the value dimension characterizing the intensity and direction of the psychological concepts. Product evaluation takes into account the various dimensions of the beliefs and values pertaining to a product concept and its associated attributes whereas product familiarity deals with belief dimensions only. This formulation is consistent with traditional social-psychological attitude formulations (see Fishbein & Ajzen 1975).

Recommendations for Future Research

With this eclectic theoretical orientation, some recommendations for future research are suggested.

First, more work needs to be done in the measurement area. Atheoretical measurement of product familiarity should be discouraged. The efforts of Olson and his associates are a step in the right direction. However, since valid measures rest on adequate theory, theory development of product familiarity should have the first priority. More research is needed to test different theories of product familiarity.

Second, if product familiarity is truly multidimensional, research effort should not only be directed to identifying those dimensions but also to reveal how they are differentially combined to form overall familiarity. Can we use an additive model and sum over all the familiarity dimensions? Or would a multiplicative model be more appropriate? Should there be weights placed on those dimensions? And so on.

Third, hardly any research has been conducted treating product familiarity as the dependent variable or the phenomenon of interest. What are the differential effects of dispositional variables such as cognitive needs and cognitive complexity on product familiarity? What are the various situational factors which influence product familiarity? Examples may include time factors (e.g., repetition, schedule of reinforcement), communication factors (e.g., type of message, type of source, type of communication channel), among others.

Finally, more systematic research needs to be conducted to determine the effects of product familiarity on consumer processes such as perception, awareness, attention, need recognition, information search, alternative evaluation, actual behavior, and outcome evaluation.

A MULTIVARIATE ANALYSIS OF THE PERCEPTION
OF VALUE FROM RETAIL PRICE ADVERTISEMENTS

Albert J. Della Bitta, University of Rhode Island
Kent B. Monroe, Virginia Polytechnic Institute and State University

Abstract

This study attempts to expand the scope of previous research on consumers' reactions to retail comparative price advertising. A large factorial experiment with multiple response measures examined the influence of several variables on consumers' perception of value from retail sale advertisements. The size of sale discount was found to have an interesting effect on consumers' perceptions of value. Also, the method of presenting sale information significantly influenced perceptions.

Introduction

The issue of consumers' response to price has stimulated considerable research interest in the past decade (Monroe 1973, 1977; Olson 1977). However, much of this inquiry has been directed at the price/"quality"-perception question. Except for the concept of unit pricing, one area receiving relatively little attention is the issue of presenting price information to consumers. This is unfortunate since numerous alternatives exist for presenting prices, and such information is an integral component of much retail advertising. Consequently, research into the price presentation area could have significant implications for managerial and regulatory decision-making.

Several schemes are useful for conceptualizing the problem. Jacoby and Olson (1977) have viewed price perception from the S-O-R perspective. Here stimulus variables (S) are the actual cues presented to the consumer where organismic variables (O) include those factors internal to the individual influencing the acquisition, processing, and derivation of subjective meaning from objective stimuli. These O-variables could include properties such as price awareness, subjective standards of reference and attitudes. The interaction of acquired stimuli and organismic conditions leads to responses (R) by the individual.

Clearly, presentation of an offered price qualifies as an S-variable which can significantly influence a consumer's perception of the offer. However, it should also be clear that the consumer's experiences and the context of an offering can influence perception of the offered price. Thus, price experiences over time and the prices of other products may be internalized as an O-variable to influence price perceptions. To illustrate, adaptation-level theory and empirical evidence suggest that the consumer's price experience forms a specific and quantifiable standard of reference for judging subsequent prices (Della Bitta and Monroe 1974; Nwokoye 1975).

In addition to such internalized influences, a variety of factors surrounding the price presentation (store setting, medium used to convey price information, etc.) form a context for judgment. Besides these general contextual variables, a given price presentation may be comprised of a set of more specific contextual cues also capable of influencing the meaning derived from the offered price. Walton and Berkowitz (1980) have classified these cues into comparison and semantic categories. Comparison cues are prices the advertiser references in order to provide a basis for judging the offered price. This may be a prevailing price in the market, the manufacturer's suggested selling price, or the retailer's regular selling price. Semantic cues involve phrases describing the price ("very

low"), price reduction ("significantly reduced") or amount of savings involved ("super savings"). Of course, some semantic phrases are emotionally laden while others are more neutral.

From a managerial and public policy viewpoint, a valid concern is how strongly price presentation formats influence buyers. The managerial concern is to present price information in a favorable manner while hopefully not misleading consumers about the nature of the offering. From a public policy perspective, the concern is over misleading and/or deceptive practices. In fact, in 1958 and 1964 the FTC issued a set of guides for presentation of retail price information.

Relevant Research

What is significant to note is the paucity of directly applicable research evidence to guide managers and policy makers. However, the few relevant studies available do provide some perspective. Fry and McDougall (1974) investigated buyers' perceptions of advertised sale and regular prices. Although the study probably suffered from experimental demand effects, the authors concluded that acceptance of advertised regular prices tended to vary inversely with the size of discounts. However, acceptance of the sale price as the "lowest price in town" varied directly with discount magnitude.

Barnes (1975) varied price and semantic information in a simulated newspaper advertised "sale" for unbranded products. Each presentation was ranked on a priori basis by Barnes in terms of the amount of its information content. The ranking (high to low) was disclosure of: (1) both regular and sale price, (2) sale price and the discount expressed in percentage terms and (3) only sale price. Newspaper and store type were also varied in the experiment. Dependent measures were believability of the advertisement, perceived value for the money and motivation to act. Results indicate a significant information treatment effect, with presentation format (1) above having the greatest influence on the dependent measures. Although this result is consistent with Barnes' a priori ranking of information content, one should note that such a ranking may not be valid in all circumstances. In some situations consumers may find an expression of the magnitude of the price reduction (e.g., percent off) to be more useful than knowing the specific sale price.

Keiser and Krum (1976) compared consumers' reactions to sale advertisements of different forms. In one, only sale price was shown while in a second condition both regular and sale prices were presented with the semantic phrase "one-half price sale." The authors report that the second condition influenced more subjects to perceive a "true price reduction" although the difference was not significant. Perceived truthfulness and willingness to purchase were also not significantly different between the two treatment groups. The possibility of confounding effects in this study should also be mentioned. In the presentation that disclosed both regular and sale prices, the former was set artificially high to examine consumers' reactions to overstated price savings. This element, not in the other treatment condition, may have introduced a bias into the study.

Sewall and Goldstein (1979) queried 114 catalog store

shoppers about their understanding of comparison (reference) prices used by catalog showroom retailers. They found that the vast majority clearly understood the meaning of reference price information. Also, 58 percent of the respondents understood or were explicitly skeptical (discounted the credibility) of such reference prices and regarded them as useful in their comparative shopping activities. It should also be noted that subjects can be influenced by such comparative information more than conscious responses to surveys might suggest.

Blair and Landon (1979) examined the effects of reference prices in retail advertisements for a TV and food processor using adult women in a shopping mall setting. One condition contained only the offered price while another presented the offered price, suggested list price and claimed savings. Results indicate that without reference price information subjects generally estimated savings at between 10 to 12 percent. However, advertisements with reference prices (and discounts from 16 to 36 percent) produced significantly larger perceptions of savings. Also the perceived credibility of claimed savings varied inversely with the magnitude of the claim.

Walton and Berkowitz (1980) reported a study of the effect of reference price, presentation format and several other contextual variables on consumers' price perceptions. Three products (aspirin, fan and camera) were tested at two discount levels (20% and 40%) and four information presentation formats: (1) "regular price"/"sale price", (2) "total value"/"sale price", (3) "compare at"/"our price", and (4) "x percent off"/"now only". Several dependent measures were analyzed using multivariate analysis of variance. Two particularly interesting findings are: (1) reference price effects varied across products, and (2) price information format was significant for cameras only. Here the "percent off" format (4) consistently received the lowest mean rating on all dependent measures.

Although informative, the major problem with previous studies is the lack of consistent findings. For example, Barnes' found the regular/sale price format to yield the greatest perception of value for the money. Although Walton and Berkowitz did not find this to be the case, they did observe a significant difference between the "percent off" format and all others. The two studies also show a similar contrast regarding the influence of information treatments on subjects' willingness to purchase. In addition, while Blair and Landon found the regular/sale price format to influence perceived savings, Walton and Berkowitz were unable to distinguish this influence from two other presentations. Discrepancies also appear between the findings of other studies.

Differences in test conditions may explain some of these divergent findings. Studies have varied in terms of the discount levels, information formats and dependent measures used. Further, they have tested different product classes, branding conditions and price levels. Additional research that accounts for some of these contextual influences is warranted.

The Study

This study investigated the influence of specific price presentation formats on consumers' perceptions. The focus was on a sale situation that consumers might confront in a retail setting.

Research Method

Prior to the experiment, content analysis of major metropolitan newspapers and catalog advertising revealed the frequency with which various components of sale information were employed. Four components were chosen for

investigation based on their frequency of occurrence: regular (non-sale) price, sale price, percentage price reduction, and absolute dollar amount of price reduction. Because previous research suggests that the influence of price presentation format could be effected by the price level and discount size, these factors were also incorporated.

A 2x5x8 factorial experimental design was used. The respective factors were comprised of two price levels, five discount levels (10% to 50% in 10 percentage point increments) and eight presentations of regular price (RP), sale price (SP), percent off (PO) and amount off (AO) information. The specific treatment levels are (1) SP; (2) RP, SP; (3) RP, AO; (4) RP, PO; (5) RP, SP, AO; (6) RP, SP, PO; (7) RP, AO, PO; (8) RP, SP, AO, PO.

A calculator was used as the experimental product because of its familiarity and potential interest to college students who were employed as subjects. Two specific models were used at regular suggested price levels prevailing in the market at the time (\$120 and \$50). The 400 participating subjects were randomly assigned (five per cell) to the 80 treatment conditions. All subjects were instructed to assume that they saw the provided advertisement which described the product and exposed them to the price presentation format. They were then asked to read the advertisement and respond to a series of dependent measures and personal background/debriefing questions.

The majority of price investigations have only examined a single dimension of buyers' response to price. However, since price presentations have potential for affecting a variety of buyer reactions, single variable studies forego opportunities to explore the potential richness of buyers' multidimensional responses to price presentations (Engel, Blackwell and Kollat 1978; Jacoby 1978; Wind and Denny 1974). This study focused on three response variates: perceived savings, perceived value for money at the sales price and perceived acceptability of the offer. These variables were selected because of a desire to concentrate attention on the perceived worth construct identified in other work (Szybillo and Jacoby 1974; Walton and Berkowitz 1980) and the attention given to the three variables in over nine previous investigations. Each of the three dependent variables was measured on a seven-point equal-interval scale anchored by descriptive phrases appropriate to the variable involved.

Analysis and Results

Preliminary analysis revealed that the three dependent variables exhibited substantial intercorrelations ($r \geq .58$). The three variables were also evaluated for internal consistency using Cronbach's (1951) alpha criterion. The resulting alpha value of 0.81 is quite large for this type of basic research (Nunnally 1967), suggesting high consistency among the response variates.

In cases where multiple response measures are correlated, separate univariate analysis of variance (ANOVA) runs on each dependent variate can lead to incomplete and/or inappropriate conclusions (Green 1978; Tatsuoka 1971; Wind & Denny 1974). For this reason a multivariate analysis of variance (MANOVA) procedure as summarized in Table 1 was selected. Wilks' Lambda is an appropriate statistic for examining differences among group centroids when two or more dependent measures serve as the joint set of evaluation criteria. The distribution of the F-statistic is proportional to the distribution of Lambda and is employed as the test statistic.

A first point of interest in Table 1 is that all interaction terms are nonsignificant. This allows direct assessment of main treatment effects as opposed to examining the influence of treatments at individual values of the other factors.

Table 1
Summary of MANOVA Results

Source of Variation	Wilks' Lambda	F-Value ^a	Probability
A. Price Level	0.9875	1.34 (3,318)	0.2591
B. Size of Discount	0.7843	6.74 (12,841)	0.0001
C. Sale Information	0.8671	2.22 (21,913)	0.0014
A x B	0.9883	0.31 (12,841)	0.9872
A x C	0.9427	0.90 (21,913)	0.5864
B x C	0.7520	1.13 (84,952)	0.2023
A x B x C	0.7847	0.96 (84,952)	0.5891

^aDegrees of freedom are indicated in parenthesis under each F-value

As shown in Table 1, price level treatments did not produce a significant difference in subjects' perceptions. However, examination of the group centroids suggests some tendency for subjects to perceive less value for the money in the more expensive model of the test product.

Table 1 also reveals that discount size and information treatments generated significant differences in subjects' perceptions. For these situations it is appropriate to engage in further analysis to isolate the nature of the differences. While a variety of techniques can assist in this exploration (Green 1978; Hair *et. al.* 1979; Tatsuoka 1971) these data were further analysed using a simultaneous confidence interval approach to multiple comparison tests (Morrison 1976). This approach to follow-up testing for a MANOVA is highly conservative since it holds a maximum alpha level for all possible comparisons of a given type. Therefore, the actual alpha level on a given test can be quite small, requiring a considerably large value for the computed test statistic. For this reason, and the exploratory nature of the research, differences that approached significance at the five percent probability level are discussed along with those that actually achieved significance.

FIGURE 1
Mean Responses to Discount Treatments

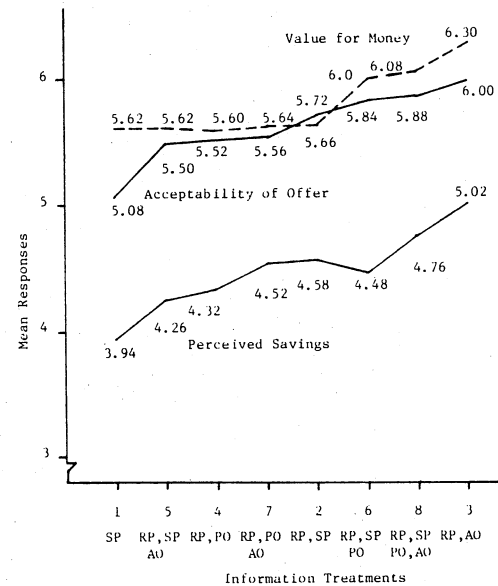

As can be seen in Figure 1, the general pattern of the three dependent variables is to increase as the magnitude of the discount increases. Significantly higher savings were perceived at the 50, 40 and 30 percent discount levels than at the 10 percent level. The 50 percent level also produced significantly higher perceptions of savings than the 20 percent treatment condition.

Larger discounts also increased the general level of perceived offer acceptability and value for money at the sales price. As Figure 1 shows, the one exception is at the 20 percent discount level where, relative to the 10 percent level, perceived offer acceptability and value for the money dropped slightly. In fact, the only group differences that approached or achieved significance on these measures were the difference in responses to the 20 percent and 50 percent-off treatments.

Since the information format treatment produced significant differences these responses were also explored through construction of simultaneous confidence intervals. Mean response patterns for the three dependent measures are presented in Figure 2. Information treatments have been arranged on the X-axis so that responses are generally increasing with movement along the axis. Also, since information treatments differed in non-quantitative aspects, their presentation on the X-axis represents categories of a factor rather than values of a continuous variable.

FIGURE 2
Mean Responses to Information Treatments

The difference between responses to information treatment one ("sales price" only) and three ("regular price and amount off") was accepted as significant for the perception of savings measure. As shown in Figure 2, treatment condition three accounted for a higher level of perceived savings. It also produced a nearly significantly greater perception of offer acceptability than did treatment one, and it accounted for the second largest mean difference on the perceived value for money measure. Further, the difference between mean responses to treatment four ("regular price and percent off") and three ("regular price and amount off") approached significance for perceived value for money with treatment three producing higher responses.

It is also useful to examine the pattern of responses as the character of information changes while the number of inputs in the advertisement remains constant. Figures 3 and 4 portray mean responses to two and three informational

FIGURE 3
Mean Responses to Two Information Treatments

inputs respectively. As Figure 3 shows, the pattern of responses to two inputs is quite consistent across the three dependent measures. The highest responses are under conditions of "regular price and amount off" information. This was followed by responses to the "regular price and sales price" treatments while the "regular price and percent-off" treatment generated the lowest level of perceptions.

FIGURE 4
Mean Responses to Three Information Treatments

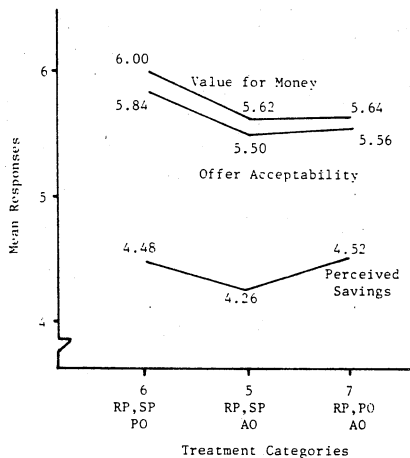

Figure 4, where responses to three informational inputs are portrayed, again shows a quite consistent pattern across the dependent measures. However, this pattern is not consistent with responses shown in Figure 3 where provision of "amount off" information as the second input led to the highest level of mean responses. That is, for three informational inputs the provisions of "amount off" information in conjunction with "regular price" and "sales price" tended to depress responses below those obtained when "percent off" information was presented with "regular price" and "sales price" information.

Discussion

This experiment was designed to investigate how individuals respond to comparative price advertisements under various conditions. The conditions involved different original

price levels, discount magnitudes and formats for presentation of price information. Response measures were perceived savings, value for the money at the sale price and offer acceptability.

Price level (\$120 vs. \$50) did not have a statistically significant effect on subjects' perceptions. However, there was a tendency to perceive more value for the money in the less expensive unit. This may suggest that the lower priced-lined unit more clearly matched the perceived needs of subjects than the higher priced model which contained more sophisticated features.

The magnitude of price discounts did produce significant differences in perceptions. Although all three dependent measures showed a very similar pattern of responses, the perceived savings variate accounted for most of the significant difference. This result closely resembles, and further confirms, the findings of Walton and Berkowitz (1980) regarding the effects of price discounts.

It is interesting to examine the character of savings perceptions across levels of price discounts. Significant differences occurred between the 10% and 30-50% levels and between the 20% level and 50% level. However, response differences between the 30%, 40% and 50% levels were not significant. This result might be attributable to subjects being suspicious of the larger discount offers. However, a separate question asked subjects to indicate the degree to which they suspected the truthfulness of the advertised prices. No significant differences in the perceived credibility of offers was detected across discount levels. Therefore, the argument that subjects' suspicions accounted for different responses to discount levels is not strongly supported. Conversely, it is interesting to observe that the threshold of significant differences in perceived savings occurs in the neighborhood of the 15% price reduction that many retailers believe must be achieved to attract consumers to a sale.

The method of presenting sale price information produced significant differences in subjects' perceptions. However, the nature of these differences appears to be complex. Presentation of only sales prices produced significantly lower perceptions of savings than did the presentation of regular price and dollar amount-off information. This result is consistent with Blair and Landon's (1979) finding that presenting only sale price led to significantly lower perceived savings than presenting reference price information with the sales price. It is also interesting to note that the average perceived savings response to all conditions employing reference price information (4.56) exceeded the average response to presenting sales price only (3.94). This shows further consistency with Blair and Landon's findings. Additionally, although the difference was not significant, format six that presented regular price, sale price and relative price reduction information led to greater perceptions of savings than when only sales price was presented. This mirrored Keiser and Krum's (1976) findings for these information presentation conditions.

Although price information formats did not significantly influence perceptions of offer acceptability and perceived value, the pattern of these responses closely reflected the perceived savings responses just described. Again, results are consistent with Barnes' (1975) findings where presentations using regular and sales prices produced significantly higher perceptions of value than expressions involving only sales price (with semantic phrase) or sales price with relative price reduction information.

When examining the effect of various price presentation formats while controlling for the amount of informational inputs, no significant differences occurred, although a rather inconsistent trend of responses was observed. For two informational inputs, presenting regular price and price reduction information in absolute terms yielded the highest

response levels across all three variates, followed by presentation of regular and sales prices. Presenting regular prices and the discount expressed in percentage terms yielded the lowest response levels. However, for presentations involving three inputs the regular price, sale price, percent-off format generally yielded the highest response levels, while the regular price, percent-off, amount-off format was only marginally higher than the regular price, sale price, amount-off format. No clear response pattern emerges from this analysis especially when comparisons between two and three informational inputs are attempted. Therefore, results suggest that while a variety of presentations involving more information than just current sales price may favorably influence consumers' perceptions of savings, offer acceptability and value for money, the relative effectiveness of these inputs is presently unclear. Further research is needed across additional subject pools, product categories and price presentation formats.

THE EFFECT OF GENERIC PRODUCTS ON CONSUMER PERCEPTIONS AND BRAND CHOICE¹

John J. Wheatley, University of Washington

Abstract

Consumer perceptions of the quality of national and private brands are apparently altered when generics are introduced in at least some product categories. National brands sales could be hurt by the improved quality image of private brands while the private brands could be adversely affected because generics offer even greater price savings to price conscious buyers.

Introduction

Generic food products were first introduced into supermarkets in the United States in 1977. They are now offered to consumers in thousands of food stores and many consumers seem to have been willing to try them. They have garnered a significant 11% market share in product categories in which they are available, suggesting that many consumers are satisfied with the quality of at least some generics (Yao 1979).

While the impact of generics on both manufacturers of "national" brands and retailers or "private" brands has been acknowledged and there has been a substantial amount of discussion and publicity given this now not-so-new development in the trade press, there has been very little attention paid to this significant change in consumer behavior by academicians. Sarel and Sewall (1980) point out what does exist "provides a mostly descriptive perspective of current position and trends." The study by Murphy and Laczniak (1979) is typical. It consisted of a telephone survey of supermarket shoppers dealing with their opinions and behavior with respect to generics. Frequency of purchase, what the respondents reported they had been buying prior to purchasing generics and future buying plans were the sorts of issues examined. Strang, Harris and Hernandez (1979) using personal interviews with shoppers in a supermarket chain determined the proportion buying generics, their income levels, the reasons given for purchase or non-purchase and shopper perceptions of the quality of generics.

No research has been reported to date dealing with consumer perceptions of specific generic products or with explaining the effect on consumers' choice behavior of introducing generics into the marketplace. The purpose of this paper is to explore these two issues.

Pragmatic and Theoretical Considerations

The generic food products that are being offered to consumers all have certain characteristics in common. They are without brand names, in very plain packages with simple labels and usually sold at prices below both the national and private brands with which they compete. The price differential is typically on the order of 10%-35% below the national brands, and 10%-20% below the private brands, but sometimes it may be as much as 65% below manufacturer's brands (Strang, et al. 1979). Occasionally, however, when national and/or private brands are on sale they may be priced below generics.

It appears that many retailers have introduced generics in order to attract price conscious shoppers on the one hand while other food retailers have added them to their product mix as a defensive measure in order to keep from losing patrons to both the low overhead "box stores" and to those merchants who initiated the introduction of generics.

Notwithstanding the trade press reports that national brands in particular have been adversely affected by the introduction of generics or the expectation that generics would take sales primarily from private brands (Strang, et al. 1979), it seems logical to suppose that both national and private brands will lose market share to generic products.

While it is plausible to believe that national brand buyers are basically quality seekers and many consumers purchasing store brands are attracted by the fact that private brands usually sell at lower prices, it seems reasonable to suggest that a significant proportion of both groups would reassess their purchase decision when confronted with an expanded choice set. A theoretical basis for expecting an altered decision making process is the fact that, as Berelson and Steiner point out (1964, p. 154):

Judgments . . . are . . . made within a frame of reference established by the total range of the relevant stimuli. For example, when the total range of light varies from x to 2x, a stimulus at 2x will be considered white; but when the total range goes from 2x to 4x, 2x will be seen as black and 4x as white.

Thus, consumers' perceptions of both national and private brands could be altered by the addition of a generic product offered at a lower price.

Helson's (1964, p. 54) adaptation level theory offers a more elaborate explanation of this phenomenon. The theory postulates that individual attitudes, judgments and behavior are the result of adaptation to environmental forces. It assumes that a new stimulus is judged on the basis of what has gone before and further that a person has adapted to those prior stimuli and internalized them. However, as Helson says:

Adaptation is . . . a two way affair. Effects of stimulation [also] initiate changes within the organism. These changes adapt the organism to prevailing [emphasis added] conditions.

In other words, a consumer might be expected to alter his or her perceptions of an existing brand when confronted with "appropriate" information such as the existence of a new "brand" selling at a lower price. This new information will be assessed on the basis of the person's existing level of adaptation. (Adaptation level may be conceived as a point of perceived neutrality; it is a kind of "average" of all the relevant stimuli to which consumers have been exposed to in the past.) Thus, a new stimulus will be compared to this neutral anchor point to arrive at an assessment and simultaneously, *ceteris paribus*, the stimulus will push the neutral point in its own direction.

In the context of a situation in which a less expensive product is added to an existing choice set, it seems logical to expect that those individuals looking for low prices would be likely to select the generic alternative, while those seeking what they perceived to be high quality would

¹The author wishes to thank his colleagues, especially K. Pettit, D. MacLachlan, R. Yalch and J. Chiu, for their helpful comments on an earlier draft of this paper.

continue to choose the national brand. However, adaptation level theory would lead to the expectation that once the private brands were under-priced by a generic alternative, the store brands should have a tendency to lose their "bargain" image and instead be viewed as "moderately" priced by some consumers. In other words, the perception of the price of the private brand would be altered; it would no longer be "cheap" and, since it has been demonstrated that price serves as a cue to perceptions of product quality (Raju 1977, Valenzie and Eldridge 1973, Wheatley and Chiu 1977), a proportion of the national brand buyers could decide to switch to the private brand because of its enhanced quality image. In addition, some previous private brand purchasers would be satisfied with the quality-price characteristics of the store brand and would remain loyal to it. Thus, the impact of generics might look something like Figure 1.

FIGURE 1
Brand Shares

Of course, this conceptualization of the consequences of introducing generic brands does not encompass all possible outcomes. For example, some national brand users might be inclined to try a generic product just to see what it was like while others might find themselves encouraged to do so because it represents a way of coping with an inflation induced reduction in their real incomes. Some essentially random brand switching would also take place.

Following the insightful observation by Leavitt (1954) that perceived differences among brands in a product class leads to the utilization of price as a cue to product quality, it also seems plausible to suggest that consumers who believe that there is little or no difference in quality among brands would be more likely to purchase the less expensive private brand in the two-alternative choice situation and to switch to generics when they are available. Those consumers who feel that there is quite a lot, or a great deal of difference, among brands in a particular product category on the other hand should tend to do just the opposite.

This behavior would also be consistent with Rao's (1972) suggestion that consumers try to maximize perceived quality per unit price paid. Minimizing price for a given level of perceived quality, a strategy likely to emerge in a recession and in periods such as the late 1970's when the real incomes of many consumers have declined, would be a logical course of action for consumers who perceive the quality of generics or private brands to be essentially equal to that of national brands.

Research Hypothesis

This line of reasoning led to the development of the following hypotheses:

1. H_0 There will be no alteration in consumers' perceptions of private brands as a result of the introduction of generic products to a choice set.
- H_A Consumers' perceptions of private brands will be enhanced as a result of the introduction of a generic product to a choice set.

2. H_0 There will be no differences in brand choice behavior attributable to perceived differences in quality among brands in a product class.
- H_A There will be a positive correlation between the price of the brand chosen and perceived differences in quality among brands in a product class. The greater the perceived difference, the more likely the consumer is to choose a higher priced brand.

Procedure

A complete list of the generic products carried by a large food chain in a Western city was obtained and six of them were selected randomly for the purpose of this investigation. Those chosen were: catsup, canned peach halves, canned pork and beans, shortening, tea bags, and canned whole tomatoes.

The six products were displayed on a table in one of the chain's stores. The actual prices at which the products were being sold in the store were indicated on each product. Every third person entering the store was intercepted and asked to participate in a survey. A total of 75 randomly assigned respondents were presented with a display of the six products which contained only the leading national and the store's private brand of each product. A second sample of 75 subjects were shown another product display that included a national, a private, and a generic "brand" of each product.

The work was carried out between 4 and 8 p.m., on a consecutive Wednesday and Thursday. The position of the various brands in the product display was rotated for both groups of respondents to avoid a position bias effect.

Each respondent was asked to indicate which one brand they would purchase in each product category and the reason for their choice. They were also asked about their perceptions of the quality of each of the brands of one of the product categories in the display.

Results

The results of the choices made by the two groups are summarized in Table 1. Two significant observations may be made about the findings.

First, it would appear that the effect of generics on national and/or private brands varies and is product specific. This finding is consistent with Sarel and Sewall's (1980) observation that market shares for generics vary substantially, e.g., 27.3% for paper and plastic plates to 4.5% for canned tuna. It is also quite possible that the effect depends on the strength of the consumer franchise held by the national and/or private brands in a product category. The national brand of catsup was not much affected by the introduction of a generic alternative, but the private brand was hit very hard. On the other hand, both the national brand and the store brand were about equal contributors to the share-of-market gained by the generic brand of tea bags.

Second, notwithstanding the fact that generics seem to gain market share at the expense of both national and private brands, private brands were bigger losers overall in this sample.

The proportion of the subjects choosing the generic, when it was available, is larger than was anticipated on the basis of market share data. One possible explanation for this is that at least some food shoppers are still unaware of the availability of generics while all of the subjects in this experiment were made aware of their existence by virtue of the product display that they saw. It is also

true as Cagley, et al. (1980) point out generics can average a 30% market share when they are featured by a food chain.

TABLE 1
Brand Choice

		National Brand	Private Brand	Generic Brand	Number of Non Users
Catsup	n ₁ =67	77.6%	22.4%	--	8
	n ₂ =72	69.4%	4.2%	26.4%	3
Peaches	n ₁ =51	31.4%	68.6%	--	24
	n ₂ =63	34.9%	31.7%	33.4%	12
Pork and Beans	n ₁ =53	60.4%	39.6%	--	22
	n ₂ =61	52.5%	19.6%	27.9%	14
Shortening	n ₁ =58	63.8%	36.2%	--	17
	n ₂ =65	47.7%	15.4%	36.9%	10
Tea	n ₁ =58	63.8%	36.2%	--	17
	n ₂ =53	45.3%	17.0%	37.7%	22
Tomatoes	n ₁ =65	47.7%	52.3%	--	10
	n ₂ =65	36.9%	29.2%	33.9%	10
Total	n ₁ =352	58.2%	41.8%	--	
	n ₂ =379	48.3%	19.3%	32.4%	

One product, shortening, was selected from the group of six to deal with the two research hypothesis.

Table 2 reveals the reasons given by the respondents for choosing shortening.

TABLE 2
Selection Reason When the Generic Brand Is or Is Not Available - Shortening

	No Generic	Generic
National		
Price	0.0 %	--
Brand Loyalty	54.1 %	58.1 %
Quality	27.0 %	32.3 %
Name Brand	16.2 %	6.5 %
Other	2.7 %	4.5 %
Private		
Price	95.2 %	50.0 %
Brand Loyalty	0.0 %	20.0 %
Quality	4.8 %	20.0 %
Name Brand	0.0 %	--
Other	0.0 %	10.0 %
Generic		
Price	--	95.8 %
Brand Loyalty	--	--
Quality	--	--
Name Brand	--	--
Other	--	4.2 %

The null hypothesis of no alteration in consumer perceptions of private brands as a result of introducing generic products can be rejected. As anticipated, the proportion of participants claiming that the private brand was

selected for price reasons declined from 95.2% to 50% when the generic product became an element in the choice set. This was statistically significant at $p < .01$. Similarly, the proportion mentioning quality as a reason for choosing the store brand rose from 4.8% to 20%. The image of the private brand was altered; a sizeable proportion of shoppers who selected the private brand now saw them as offering quality and fewer saw them providing price savings.

Finally, the reason given for selecting the generic product was almost unanimously because of its lower price.

The subjects were asked to indicate if they felt there were any differences in quality among brands of shortening and how big these differences were. They were asked to use a 5 point scale with 1 representing no difference, 2 very little difference, 3 some difference, 4 quite a lot of difference, and 5 a great deal of difference.

It was anticipated that the beliefs held by consumers concerning quality differences among brands in a product class would affect choice behavior. If a buyer believed that the differences were small they would choose the least expensive alternative, i.e., the private brand in the two choice set and the generic in the three choice set. However, if the differences were believed to be large, such persons would be more likely to avoid the low price alternative.

The null hypothesis of no difference in brand choice behavior attributable to perceived differences in quality among brands can also be rejected, in part.

The results in Table 3 indicate, as predicted, that in the three alternative choice situations, those consumers choosing the national brand believed that the quality differences among brands of shortening was greater than the differences perceived by those choosing either the private brand or the generic. A pairwise comparison of the means revealed that the difference was large enough to be statistically significant, $p < .05$. While the perceived difference in brand quality between those choosing the private brand and those selecting the generic is in the expected direction, the difference between them is not statistically significant.

TABLE 3
Mean Perceived Differences Among Brands of Shortening*

	Consumers Choosing the National Brand	Consumers Choosing the Private Brand	Consumers Choosing the Generic
3 alternatives	3.31	2.60	2.38
2 alternatives	3.28	2.41	

* 1 represents no difference and 5 a great deal of difference

In the two alternative conditions the perceived quality difference between those choosing the national brand and those selecting the private brand is also significant at $p < .01$.

Limitations

Although the subjects in this exploratory study were allowed to indicate that they did not use the products shown to them or did not wish to indicate a purchase preference they were confronted with what some of them may have felt was a forced choice situation. They were also shown only one national brand in each product category and the experiment was conducted in a single store.

Furthermore, two different samples were used rather than a single sample of subjects.

Finally, in connection with the second alternative hypothesis, the tendency to choose the national brand was probably enhanced due to the fact that the subjects did not have to make an actual purchase.

Conclusions

The introduction of generic products into supermarkets appears to affect consumer behavior in a complex manner. Consumer perceptions of prices and the price-quality ratio or "value" of national and especially private brands can apparently be altered when generics are introduced in at least some product categories. Sales of national brands could therefore be hurt by the improved quality image of private brands while the private brands could be adversely affected because generics offer even greater price savings to price conscious buyers. In other product categories, specifically those in which consumers perceive only small quality differences among brands, it seems likely that this effect may not materialize, at least to the same extent.

Consumer's beliefs about differences in quality among brands in a product class appear to influence consumer behavior too but in a more straightforward manner. Those who perceive large differences tend to choose national brands presumably because they think that national brands are of better quality than retailer's brands or generics. (While most observers agree that there are quality differences among national, private and generic brands, there is very little objective evidence available on this point.) Those individuals perceiving smaller differences choose private brands while those who perceive the least difference among brands tend to choose generics.

Parenthetically, it would seem that the advertising strategy of some national brand manufacturers and retail food chains of stressing the quality of all their offerings as a way of blunting the inroads of generics on their share-of-market seems unlikely to succeed with those consumers who feel that all brands in a product class are very much alike.

It is to be hoped that the results reported here will interest other researchers in pursuing this subject further. Especially useful would be an experiment confirming these findings utilizing a longitudinal, within subject design. Only in this manner can an examination of individual consumer brand switching, and the possible reasons for it, be studied.

The introduction of generics is a significant development worthy of attention simply because of the magnitude of its effect on consumer behavior and because growing environmental pressures such as inflation serve to call these products to consumers' attention with increasing frequency. It is also of considerable significance to marketers of packaged goods. If sellers wish to exercise some degree of control over this development they must try to understand the process by which consumer attitudes and behavior are being affected by generics.

This exploratory study, planned to be the first of a series, also suggests that it is an intellectually interesting and challenging phenomenon as well.

DETERMINANTS OF CONSUMPTION CUE UTILIZATION IN IMPRESSION FORMATION:
AN ASSOCIATION DERIVATION AND EXPERIMENTAL VERIFICATION

Russell W. Belk, The University of Utah

Abstract

This paper reports the results of two studies investigating the characteristics of product and service choices that tend to make these choices useful cues for inferences about the personality and social class of those who are observed consuming such items. The first study is a regression-based analysis of these determinant characteristics across a set of 39 types of products and services. Utilizing three characteristics that this analysis suggested are the strongest determinants of the usefulness of these product and service choices in impression formation, the second study experimentally varied the characteristic properties of a single consumption item choice in order to verify the results suggested by the regression model. The results tend to support the utility of cost and decision involvement as determinants of the item's influence on impressions about its user, but did not support a similar influence from the amount of variability in the choice set.

While a person's choice of products and services is certainly not the only source of cues for assessing that person's character and position in society, certain choices that are visible to others may be among the only cues available when observers encounter someone with whom they have had little or no prior interaction.¹ Although there has been little formal investigation of the role that consumption choices play in communicating information about the consumer to others², it seems clear that certain consumption choices such as furniture and clothing selections are generally perceived to be more expressive than other consumption choices such as insurance and menu selections. The particular choices among items within a product or service category may convey different consumer information depending upon factors such as the item's color, style, brand name, and condition. In addition some types of products and services may be better cues to the consumer's characteristics than others because, for instance, they are more familiar, costly, unique, or represent a longer commitment to the choice. This paper is concerned with the identification of the consumption choice characteristics which make that choice act as a weaker or stronger cue for inferring the states and traits of consumers observed using products and services with these characteristics.

Prior Research

Because of the lack of previous research directly investigating the consumption cue attributes that result in the utilization of certain cues in impression formation, it is necessary to begin by considering the nature of products and services that have been found to influence such perceptions of people and then attempt to infer the characteristics of these consumption choices which cause them to be treated as reliable clues to personality and social class. One category of consumption cues which has been most clearly documented to affect impression formation is clothing. While we have departed from the era when only royalty were allowed to wear certain colors and fabrics such

¹Cue visibility is in fact one of the characteristics examined in this paper as a potential determinant of cue reliance.

²For reviews of the research which has been done see Belk (1978, 1980) and Holman (1979, 1980).

as sable, there is strong evidence that clothing still imparts messages concerning social status (Douty 1963; Hoult 1954; Rosencranz 1962; Laswell and Parchall 1961; Wise 1974; Sommers 1964; Dellinger 1977; Bickman 1971; Lefkowitz, Blake, and Mouton 1955; Veblen 1899). It is also clear that clothing can serve as a strong cue for inferences about other user traits and can affect subsequent actions toward these consumers (Buckley and Roach 1974; Golden, Allison, and Clee 1978; Lefkowitz, Blake and Mouton 1955; Coursey 1973; Gibbins 1969; Rosenfeld and Plax 1977; Hamid 1968, 1969, 1972; Johnson, Nagasawa and Peters 1977; Thornton 1944; Thibaut and Riecken 1955; Holman 1980, forthcoming; Darley and Cooper 1972; Suedfeld, Bochner, and Metas 1971). Automobile ownership and selection is suggested by the literature to be another product area with definite implications for inferences about the owner's status and personality (Jacobson and Kossoff 1963; Bruce-Briggs 1977; Green and Wind 1973; Doob and Gross 1968; Ferber 1962; Porter 1966; King and King 1980a, 1980b; Martineau 1957). And the literature suggests that homes or residences also commonly allow inferences about the personality and social class of their residents (Canter, West, and Wools 1974; Felk 1978; Wedin, Avant, and Wolins 1973; Verhure, et al. 1977). Furniture and furnishings within a home, even including appliances, seem to serve similar purposes for impression formation (Sommers 1964; Chapin 1935; Ferber 1962; Laumann and House 1970). Nevertheless, Felson (1976, 1978) provides evidence that suggests that at least for inferences of social status, clothing, automobiles, housing and furnishings are no longer as reliable a set of cues as they were in earlier decades in the United States. Blumberg (1974) has suggested that such a decline in the usefulness of certain consumption cues for inferences of social status (and we may speculate, for inferences of personality traits as well) may be due to rising availability of such goods and declining constraints of income on the ability to choose freely within these product classes. This explanation also finds some support in extensions of Brock's (1968) commodity theory that support the hypothesis that scarcer goods are better able to convey messages concerning the status or uniqueness of the consumer (Fromkin, Olson, Dipboye, and Barnaby 1971; Szybillo 1975; Worchel, Lee and Adewole 1975). Thus one key feature of product and service choices which appears to affect their utility as cues for impression formation is their current uniqueness.

Among the other product and service choices that have most frequently been found to alter inferences about the personality and social class of consumers are cosmetics (Calder and Burnkrant 1977; McKeachie 1952; Belk 1978; Sommers 1964; Golden, Allison, and Clee 1978), books and magazines (Green and Wind 1973; Porter 1966), foods (Haire 1950; Belk 1978; Woodside 1972; Sommers 1964), and leisure products and activities (Porter 1966; Belk 1978; Bishop and Ikeda 1970; Sommers 1964). One factor these consumption categories seem to have in common is that they all provide a large number of substantially different choices. Without the freedom to make distinct choices which this characteristic provides, there would be little information conveyed in a consumption choice. Thus the variety of choices available may be a second determinant of the reliance placed on a particular product category in forming consumption-based impressions of others.

Several additional cue attributes appear to be related to consumption-based impression formation when the literature

cited is carefully examined. One such cue attribute, especially for inferences of social status, is the cost of the consumption item. Generally the more costly the item, the more related it seems to be to inferences about social class. Two potentially related cue attributes which may nonetheless be independent of cost in many cases, are the length of time to which the consumer is committed to a choice and the amounts of time and thought that go into the selection decision. Here it would be expected that where there is a more long-term commitment to the product choice (e.g., choice of colleges versus choice of restaurants) and where the decision is commonly more carefully thought out (e.g., choice of magazine subscriptions versus choice of television programs), the choice will be a more reliable cue to inferences about the consumer, especially that consumer's personality.

For more axiomatic reasons it may be seen that another property related to the use of the foregoing consumption cues is their visability or noticeability. A cue must be able to be detected before it can possibly have any effect on impression formation. While the consumption items found to serve as cues differ in their visability, they are all more visible than, for instance, underwear or furnaces. Two exceptions distinguishing visability from noticeability may be the cases of innovations and gifts. In both instances items that may not normally be visible may become evident through heightened interest and conspicuous display.

Two final cue properties that may elevate consumption choices to the status of consumption symbols are the complexity and the rate of stylistic change currently associated with the item. Complexity may be capable of endowing a consumption choice with surplus meaning about its consumers because of the objective ambiguity created when a product or service is beyond most observers' ability to fully understand and objectively evaluate. In these circumstances the choice not only evokes a degree of mystery, it also may give rise to more subjective inferences than would be likely for a simpler product. A product or service subject to frequent or substantial style changes may produce a similar atmosphere of mystery and subjectivity because its selection is presumably more "a matter of taste," and such tastes presumably stem from personality and social class.

In summary, a consideration of possible reasons why a scattered literature suggests that only certain product and service selections are commonly related to inferences about their owners led to hypotheses about eight consumption cue attributes. Consumption choices are predicted to be more useful to inferences about the social class and personality of their users when these choices possess or involve: uniqueness, variety, high cost, long-term commitment, thoughtful selection, noticeability, complexity, and stylistic change. All eight of these characteristics were investigated associatively in Study 1 which acted as a screen on the characteristics to be investigated experimentally in Study 2.

Study 1

Method

Sixty-eight undergraduate students were drawn from first year business students at the University of Illinois in both studies. All 68 completed ratings of the 39 products and services shown in Table 1. The products were broken into three sets to avoid fatigue and were rated by subjects on the eight characteristics derived above using a 5-point scale of agreement that a selection from the product or service category was _____.³ In addition each product or

³The attributes are shown in Table 2 as they appeared in the data collection instrument.

service was rated on the same scale as to whether it was "a good clue to personality" and whether it was "unrelated to social class".

Two types of regression analyses were conducted using the 39 products or services as observations, personality or social class ratings as dependent variables, and the eight other ratings as predictor variables. In the first type of regression the mean scores over subjects were used for both the dependent and predictor variables. In the second type of regression, 68 separate regressions were run for each dependent variable, using the scores of one subject at a time. The two sets of results were then compared.

TABLE 1
Products/Services and Examples Used in Study 1

1. Outerwear (e.g., sweatshirt, windbreaker)
2. Residence (e.g., apartment, dormitory)
3. Furniture (e.g., modern, colonial)
4. Credit Card (e.g., American Express, Visa)
5. Department Store Charge Card (e.g., Zayre, Penny's)
6. Pet (e.g., dog, cat)
7. Main Course (e.g., fish, steak)
8. Cosmetics (e.g., green eyeshadow, tan eyeshadow)
9. Automobile (e.g., sedan, station wagon)
10. Transportation (e.g., bus, train)
11. Entertainment (e.g., bar, movie)
12. Stereo (e.g., component, console)
13. Religion (e.g., Mormon, Protestant)
14. Ring (e.g., classring, turquoise stone ring)
15. Swimming Suit (Male: e.g., boxer style, brief style)
16. Watch (e.g., digital, sweep-second hand)
17. Eyeglasses (e.g., wire rimmed, horn rimmed plastic)
18. Hair Care (Male: e.g., barber, hair stylist)
19. Bicycle (e.g., ten speed, one speed)
20. Facial Tissue (e.g., 1-ply, 2-ply)
21. Camera (e.g., 35mm, pocket instamatic)
22. Laundry (e.g., coin-operated, over-the-counter)
23. Toothpaste (e.g., flouride, whitening)
24. Underwear (Male: e.g., boxer style, brief style)
25. Underwear (Female: e.g., brief style, bikini style)
26. Attache Case (e.g., brown Naugahyde, brown leather)
27. Life Insurance (e.g., term, whole life)
28. Flowers (e.g., cut, potted)
29. Book (e.g., Huckleberry Finn, Fear of Flying)
30. Newspaper (e.g., Wall Street Journal, News Gazette)
31. Magazine (e.g., Time, Readers Digest)
32. Winter Recreation (e.g., cross-country skiing, snowmobiling)
33. Cigarette (e.g., low-tar, regular)
34. Gum (e.i., bubble, sugarless)
35. Overnight Accommodations (e.i., hotel, motel)
36. Shoes (e.g., dress, athletic)
37. Telephone (e.g., desk phone, slimline phone)
38. Television (e.g., color, black and white)
39. Boat (e.g., sailboat, motor boat)

Table 2 shows a summary of the mean scores regression analysis for the two dependent variables. While there is some multicollinearity in the data, the full equations showed four partially overlapping variables to be significant predictors of both dependent variables. The three shared predictors were variety, thoughtful selection, and high cost. In addition, noticeability was strongly significant in the personality equation and uniqueness was a significant predictor in the social class equation. As expected, all but the one non-significant simple correlation coefficient (uniqueness with personality) were positive, showing that the hypotheses derived from the literature are substantially correct according to the average judgments of these subjects.

In the 68 within-subject regressions, the results are highly supportive of the mean scores regression. These results are summarized in Table 3.

Average Adjusted R ²	.38		.29	

¹ p < .05 ² reverse scoring of "unrelated to social class"

In fact, the numbers of positive beta weights are in almost exactly the same rank orders over the eight predictor variables as the rank orders of beta weights in the mean score regressions summarized in Table 2. This lends strong support to the conclusions that products available in greater variety, involving more thoughtful selection, and costing more are thought to be better clues to personality and social class, and that personality inferences are also based on more noticeable consumption cues just as social class inferences favor more unique cues.

Because of the intercorrelations of the predictor variables no claim can be made that each of the significant variables in the regression equations is a better predictor than each of the non-significant variables. However we can be more confident that the significant predictor variables which are shared for the two dependent variables are judged to be strong cues to personality and social class even when the other variables are taken into account. But this conclusion is based on judgments of cue usefulness rather than actual utilization of these cues, is based on judgments of cue attributes rather than objective differences in cue attributes, and is based on associational evidence

rather than an experimental investigation. Therefore the second phase of this research took the three best shared predictor variables found in the regression study (variety, decision thought, and cost) and sought to test their ability to alter actual impression formation in an experimental context.

Study 2

Method

The three consumption cue properties identified to be predictors of social class and personality were investigated in a 2 x 2 x 2 factorial experimental design. In order to gain additional control over extraneous variables all three predictors were manipulated in the context of a single product—an attache case. Business student subjects were asked to attempt to describe the market which they felt would be attracted to a new attache case to be marketed by a luggage specialty store. The further description of the store and product contained the manipulations. The following description shows the two levels of cost, selection involvement, and variety respectively:

A luggage specialty store will be selling a new attache case made by Samsonite next month. The attache case is medium in size and comes in tan naugahyde. The suggested retail price is \$29.95 [59.95], which is an average price for an attache case today. This particular case incorporates the new slim look with hidden latches and minimal hardware. Most attache cases including the Samsonite products change their designs and materials about every five years. The salespeople of the luggage store have noticed that most customers buying attache cases spend about 10 minutes in the store and examine 2 or 3 [30 minutes...and examine most] of the dozen [three dozen] models which the store carries, prior to deciding.

Subjects were then instructed to make their best guesses about the average demographic characteristics of customers for the new product (average age, average income, percent who are female, most likely type of occupation [7 choices arrayed by status], average education [5 levels], percent who are single, and percent who have children). Of these characteristics, three were combined into an additive index of social class for further analysis: occupational status (level from 1 to 7, multiplied by 2 to increase its relative weight), income (in thousands of dollars per year) plus education level (some high school or less = 1... advanced degree = 5). In addition, subjects were asked to estimate typical customer personality traits on 13 bipolar adjectival scales with 7 scaling positions.⁴ Although a multivariate analysis of variance showed a significant effect on this set of ratings for the main effects of two of the three treatment variables (cost and decision involvement) it was felt that univariate analyses of variance would prove more enlightening. Since there were 10 subjects in each of the 8 cells of the experimental design, it was not feasible to conduct within cell factor analyses of scores on the 13 personality traits, so a single factor analysis with all 80 subjects was performed in order to reduce the number of dependent personality variables and increase the reliability of the measures through the use of factor scores. Table 4 shows the results of the final factor analysis retaining 4 factors that captured just over 76 percent of the variance in responses. It appears that the personality factors derived might be labeled "maturity", "likeability", "warmth", and "happiness". Factor scores for each of these four dimensions were derived using regression-based procedures. These factors as well as the social class index formed the final dependent variables for analysis of the experiment.

⁴ These adjectives were selected based on the work of Rosenberg, et al. (1968) and Schlenker (1975).

TABLE 4
Factor Analysis of Personality Traits (Varimax Rotation)

Trait	Factor Loadings			
	Factor 1	Factor 2	Factor 3	Factor 4
Friendly	-.03	.52	.24	.30
Intelligent	.71	.28	.04	-.03
Dull	-.08	-.60	-.09	-.24

Sincere	.23	.21	.33	.11
Happy	.11	.33	.02	.87
Warm	-.21	.37	.73	.28
Impulsive	-.37	.04	-.05	-.06
Creative	.30	.12	.31	.48

Results

A manipulation check was included after all other results had been collected. Based on t-tests on mean differences between treatment level means for 5-point scales to estimate the amounts of "variety available", "care and thought going into the purchase decision", and "cost" for an attached case compared to other types of purchases, all three manipulations were successful with a type I error probability of 5% or less.

Table 5 presents the results of the analyses of variance on these four personality factors and the social class index. It may be noted first that the variety manipulation was not significant as a main effect and was only marginally significant in the three-way interactions for likeability and warmth. The other treatment variables were however significant as main effects for social class and for at least two of the four personality factors. All of these effects were positive (e.g., greater cost led to judgments of higher social class). However, the interaction of cost and decision involvement for the last three personality factors shows that customers were judged to be more likeable, warmer, and happier under the combination of higher cost/less decision involvement as well as the combination of lower cost/more decision involvement.

Discussion

The regression results suggesting that cost and decision thoughtfulness (involvement) are positively related to the tendency to use a consumption cue to form judgments of the consumer's personality and social class are supported by the experimental results. Such is not the case for the selection variety available for a product or service however. Contrary to the regression results the manipulated levels of variety did not affect judgments of either

social class or any of the four personality factors derived.⁵

While these results can be properly taken as strong evidence that the cost and decision involvement in selecting a product affect the likelihood that the selection will be used in forming social class and personality impressions of the product user, they should not be considered to be strong evidence that decision variety (or any of the other significant cue properties from the regression model) is unrelated to the usefulness of the consumption item in impression formation. For one thing, the untying of cue properties from the product or service category in the experimental phase of this research is artificial and, even though the manipulation checks were successful, may not have reflected the richness of differences in available variety which occur across product and service categories. Another constraint was the limited and entirely verbal information that was made available about the visual details of chosen and unchosen alternatives. Finally, the dependent variables probably do not reflect the full range of inferences which may be made about people on the basis of their consumption choices. For instance, although the personality variables were chosen from those derived by Rosenberg, Nelson, and Vivekananthan (1968) and by Schlenker (1975), they are probably not exhaustive enough to capture all of the possible nuances in the impressions formed of various product and service users.

Thus the present studies support the conclusion that products and services that are more costly and involve more carefully thought-out decisions are more likely to be utilized in forming impressions of users of these products and services. At the same time this does not rule out the possibility that some of the other cue properties investigated are also determinants of consumption cue utilization in impression formation. Specifically, the regression model suggests that the noticeability and selection variety of a product or service category enhance its usefulness for personality inferences and that uniqueness and selection variety help to determine the usefulness of product and service choices to social class inferences about consumers. In order to evaluate these predictions more fully, additional experimental testing is needed using both within- and between-product-category manipulations of the predictors.

CONSUMER PERCEPTIONS: A DISCUSSION

Eric N. Berkowitz, University of Minnesota

Abstract

The title for this session indicates the extent of commonality between these three papers. Beyond this broad framework, little overlap exists. As a result, a discussion of macro-perceptual issues is difficult. Although the presentation may be a little more tedious, I will discuss each paper in sequence.

For each paper, three questions will be addressed. First, how adequate is the design and methodology employed? Secondly, what additional information is presented in these studies which hitherto has been unknown. And, finally, I will take some liberty to suggest areas of additional research which are suggested by these papers.

Della Bitta and Monroe's "Perception of Value from Retail Price Advertisements"

The study conducted by Della Bitta and Monroe focuses upon the presentation of price information to consumers, and the effects of these presentations on consumers' price evaluations. The authors' motivation for this study is derived some extent from the inconsistencies of prior research. Findings indicate that semantic and comparison cues do affect price perceptions, but the inconsistencies of prior research are not resolved.

Methodologically, this study has a distinct strength in its multivariate treatment of consumer response variables. Advancement in pricing research necessitates this recognition of a multiple response ["R" in the Jacoby and Olson conceptualization] variable framework. There are, however, a few aspects of this design which deserve some comment and re-examination.

Of some concern in this study is the product. The use of a single product in price perception studies must be questioned. As Della Bitta and Monroe note, this research stream while still developing has resulted in several inconsistent findings. Berkowitz and Walton have shown in a multiproduct price response study that consumer perceptions may vary by product class. As a result, findings of single product pricing studies present some difficulty in interpreting their generalizability. A second aspect of the product concern is the product itself. Calculators, as a class of products, are probably highly familiar to the subject population, students. How does this familiarity affect perceptions of discount levels? Does this possible familiarity negate the effect of more descriptive comparison cue presentations? Using the S-O-R framework, the (R)esponses may be moderated by the (O)rganismic variables. Price responses may have to be analyzed in light of "O" variables such as familiarity, reference standards, ownership, etc.

The Della Bitta and Monroe study adds several interesting aspects to the knowledge of price perceptions. Foremost, this study underscores the complexity of consumer price responses and the multidimensional nature of these judgments. Results are particularly interesting in showing the consistently poor response generated by an advertisement with only the actual price cue. And, this study finds the "percent off" semantic cue to be one version which does not favorably affect price perceptions. This finding is consistent with results observed by Berkowitz and Walton (1980). Of greatest interest may be the lack

of response differences across the three highest level discount treatments (30%, 40%, 50%). This finding should imply some reconsideration of retail mark-down policies as well as of discount operations' initial price offerings.

Finally, this study raises several interesting areas of further study. No price study has provided so many possible comparison price cues. While the most descriptive alternative (RP, SP, PO, AO) did not result in the highest positive price perceptions, this more descriptive presentation should be investigated among non-student subjects. Wheatley and Chiu (1977) and Berkowitz and Walton (1980) have observed demographic differences in price perceptions. It is possible that the amount of comparison price cue information necessary to be related to positive price perceptions is dependent upon the education level or age of the respondent.

A second important area for future investigation pertains to the discount levels. Since credibility of the price offering was not found by the authors to be an issue, other explanations for this observation should be explored. Pricing strategies for practitioners might be very dependent upon this area of research.

Finally, the "O" variables of the S-O-R model deserve greater attention. What is the effect of familiarity, usage, expected price level on consumer price responses?

As usual with pricing research, while several important and interesting findings have been added to the base of knowledge, it also has the beneficial effect of suggesting several areas worthy of further exploration.

Wheatley's "Generic Products on Consumer Perceptions and Brand Choice"

The second paper in this session examines the impact of generic brands on consumer perceptions and brand selection. The objective of the study is to assess the effect of generic brands on the share of national and private brands. Wheatley reports that generic brand market share is obtained from both the national and private label, and consumer perceptions of these existing offerings also shift with this new form of competition.

The methodology of this study is unique from the other two papers in this session by its use of non-student subjects. Yet several aspects of this study raise questions with regard to the interpretation of the results. Of primary concern is the selection and meaning of "national" brands. One group of shoppers were presented with two choices (national vs. private label) in six product categories. A second group also was presented with the same six product categories, however, a generic brand was included among the stimuli. How dependent are the observed product selections on the "national" brand being presented to subjects? The national brand was described as the "leading" offering. Is this "lead" with regard to sales at the experimental store/or in terms of national market share? If the latter definition is accurate, non-national brand selection may not be surprising.

A second concern is the demand characteristics of this experiment. Wheatley hypothesizes that the selection of the generic and private label offerings in the three-

choice condition may be understated. In the Limitation section of the paper, Wheatley states "the tendency to choose the national brand was probably enhanced due to the fact that the subjects did not have to make an actual choice". A competing explanation, however, might account for an overly high frequency of generic and private label selection. A consumer confronted with three products at three different price levels and asked which one s/he would choose, might feel compelled to give the impression of rationality. This demand artifact would result in the lowest cost alternative being selected.

A third concern with regard to this study is the previously identified strength, the subjects. Some criticism might be voiced regarding the small number of subjects, yet Wheatley should be complimented for convincing a retailer to allow an in-store study. However, the subjects who did participate do not appear to have been qualified in any way. Did the subjects use any of the existing brands? For example, what percentage of the 75 subjects presented with the three choice criteria use the national brand of catsup? Does this possibility account for the little slippage of the national brand brand choice figures (in the 2 vs. 3 condition)? Results should have been analyzed with regards to existing brand usage. Had any of the subjects in the generic group had prior experience with generic products?

A final concern with this study is the in-depth presentation of only one product category. In light of the variations observed in product selection, the choice reasons should have been gathered (or reported) for all six product categories.

Results of this study are interesting in terms of the observed brand choice shifting in the three choice condition. To some extent, these results must be disconcerting to companies in going against the trade belief that generic gains will be at the expense of store brands (Coyle 1978). Moreover, the selection reasons analysis in the shortening case reveals an interesting perceptual restructuring of brand offerings. With the existence of the generic brand, the differential advantage of private labels noticeably diminishes, but a new position on the quality dimension is revealed.

Wheatley's study suggests a couple of areas worthy of further investigation. First, some attention to the problems discussed with this study might clarify the impact of generic brands. Secondly, large variations across product classes with regard to generic brand selection are observed. What are the reasons for this occurrence? Are these variations due to perceived quality differences across product offerings? What of price differentials between alternative choices? In this study, edible products were investigated. The potential for generic brand inroad may be in non-edible commodities such as paper goods. Future investigations should consider different classes of products. Several of these issues may be resolved in the near future. The author's final statements indicate more information will soon be coming.

Belk's "Determination of Consumption Cue Utilization"

The third paper of this session is the continuation of a research stream in impression formation presented at ACR. Belk's objective in this study is to identify consumption cue determinants that result in impressions of personality and social class. The extensive literature review provides eight possible determinants. A two-stage study is conducted to assess which attributes are significant in forming impressions.

To a great extent, the design of this study appears highly appropriate. Two separate subject groups were used, one to develop the possible predictions and a second to validate the cue determinants. Following the style of this study, I'd like to raise some questions by study.

Study 1 required 68 students at the University of Illinois to assess 39 products on eight dimensions as to whether the products were related to personality and social class. Similar to the first paper in this session, the student subjects may be deserving of some criticism. These subjects, students at a State University, are quite likely to be similar in terms of social class. This homogeneity in social class might affect their own evaluations on this criterion.

A second concern with Study 1 pertains to the meaningfulness of the task. How meaningful is it to rate Pets, or Flowers (e.g., cut, potted) in terms of complexity? A table showing the 39 x 8 means and standard deviations of the student ratings could help eliminate this concern.

Study 2 investigated the significance of the predictors (variety, cost, decision involvement) identified in the first portion of this research. Again, a student subject pool was used, but the product was restricted to briefcases. Several other products such as bicycles, winter recreation, televisions, in Table 1 appear more relevant to student subject 1. Why was this particular product selected for study 2? What effect might familiarity with the product have in impression formation?

Variety is not observed in study 2 to be a significant determinant. Again, the experience/familiarity of students with this product may contribute to this lack of significance. A second possible reason, as Belk also notes, may be in the operationalization of variety. The variety manipulation was done in terms of dozen [three dozen] models. The "models" term is not explained or further defined.

How does this research extend existing knowledge? Belk has provided a good first step in identifying the determinants of cue utilization. Since products have been found to affect impression formation, the identification of significant determinants is critical. Future research in this area has an important area in which to expand. The relevancy of this research in marketplace behavior has been proposed. The need to demonstrate the results of impression formation to marketplace behavior, however, could afford further demonstration.

TEMPORAL LINKS BETWEEN PREFERENCE AND PERCEPTION

James McCullough, University of Arizona
Douglas MacLachlan, University of Washington
Reza Moinpour, University of Washington

Abstract

This study examines the reliability of preference analysis using LINMAP in situations where perceptions are found to be stable over time. The results of preference analysis are shown to be less stable than perceptions but still reasonably reliable. Suggestions are made on the use of this type of analysis to understand consumer responses to information and persuasive communications.

Introduction

A major goal of promotional activity in marketing is the alteration of consumer preferences for products. In order to effectively utilize information and persuasion in promotional campaigns, it is necessary to understand how preferences are formed and what influences their change.

Marketing researchers have developed methods for examining both preference and perception. Examination of formation and change of preference would seem to necessitate examination of the link between preference and perception. Although several researchers have demonstrated the temporal reliability of measures used to measure preference and perception (Moinpour, McCullough, and MacLachlan 1976; Acito 1977; McCullough and Best 1979), attempts to link preference and perception in longitudinal studies have been limited and unsuccessful (McCullough, MacLachlan, and Moinpour 1979).

Examination of the link between perception and preference requires reliable measurement of both perception and preference, and reliable analysis of the link between the two. Individual differences scaling (INDSCAL) has been shown to be a reliable method for the analysis of consumer perceptions (Carroll and Chang 1970; Moinpour, McCullough, and MacLachlan 1976). Preference ranking is generally a reliable method for the collection of individual preferences (Acito 1977), although, as Best (1978) points out subjects need solid reference criteria to insure reliability. Linear programming techniques for the multidimensional analysis of preference judgments (LINMAP) appear to provide a suitable method for examination of the link between perception and preference (Srinivasan and Shocker 1973), but the reliability of the method has not been demonstrated.

Research Questions

This study is designed to examine the reliability of analysis of preference and perception as a tool for understanding consumer behavior. To accomplish this objective it is necessary to determine if:

1. Perceptions of unchanged stimuli can be reliably scaled at different points in time as reported in the literature.
2. Preferences are stable over time.
3. Preferences and perceptions reported at different points in time for identical stimuli can be reliably linked by joint application of preference and perception analysis.

The research reported here is an attempt to establish baseline controls for the measurement of changes in consumer perceptions and preferences resulting from informational and persuasive messages.

Experimental Method

A convenience sample of twenty-five subjects drawn from undergraduate marketing classes participated in testing sessions during which they were told they were testing the usefulness of new marketing research techniques. At each session, subjects were asked to rate all possible pairs of 10 toothpaste brands (N=45) on nine-point dissimilarity scales and to rank the brands in order of preference. The brands used in the study were chosen to match the previous study by Moinpour, McCullough, and MacLachlan (1976). Two additional brands (Aim and Aquafresh) were included to increase constraint (see Table 1). An attempt was made to replicate the previous study as closely as possible. Subjects completed this task three times at one week intervals. Twenty-four subjects completed the study, providing responses at one week intervals over a three week period.

Analysis

Pairwise dissimilarities were analyzed using the INDSCAL algorithm which produces group stimulus space coordinates and individual dimension saliences. These perceptual spaces were compared using the CMATCH algorithm (Cliff, 1966) while the preference rankings were compared using Spearman rank correlation. The group stimulus space coordinates and preferences rankings for each individual were analyzed using the LINMAP mixed mode option to produce individual dimensional weights or utilities.

Assume that each stimulus (brand) k can be represented by a vector of p coordinates

$$Y = (Y_1, Y_2, \dots, Y_p) \quad (1)$$

The INDSCAL model for measuring individual perceptions assumes the basic structure of the product space is shared by all people in the relevant market, but allows individual subjects to stretch or compress that space by a set of dimension weights or saliences. The group space coordinates

TABLE 1
Toothpaste Brands Used in Study

Aim	Gleem II
Aqua Fresh	Ipana
Close Up	Macleans
Colgate	Pepsodent [®]
Crest	Ultra Brite

by a set of dimension weights or saliences. The group space coordinates Y_{jk} for attribute j and brand k are transformed into individual coordinates X_{ijk} for individual i by the application of subject-dimension weights (saliences) W_{ij} . The algorithm developed by Carroll and Chang (1970) simultaneously derives Y_{jk} , and W_{ij} values from matrices of brand dissimilarities for all individuals using the model:

$$Y_{ijk} = (W_{ij})^{1/2} Y_{jk} \quad (2)$$

The LINMAP Model

The LINMAP is one of many "utility" generating algorithms. It has the advantage of modeling decreasing marginal

utility and ideal points for some attributes and constant marginal utility (vector model) for other attributes. It posits the following functional form for utility of brand k at time t :

$$U_{\hat{k}t}(x_k) = \sum_{j \in j_1} V_j (x_{jk} - I_j)^2 + \sum_{j \in j_2} V_j x_{jk} \quad (3)$$

where j_1 is the set of all attributes having finite ideal points and j_2 is the set of all attributes with infinite ideal points; V_j is the attribute "importance" (i.e., the value of the attribute in determining preference); and I_j is the subject's ideal point on the j th dimension.

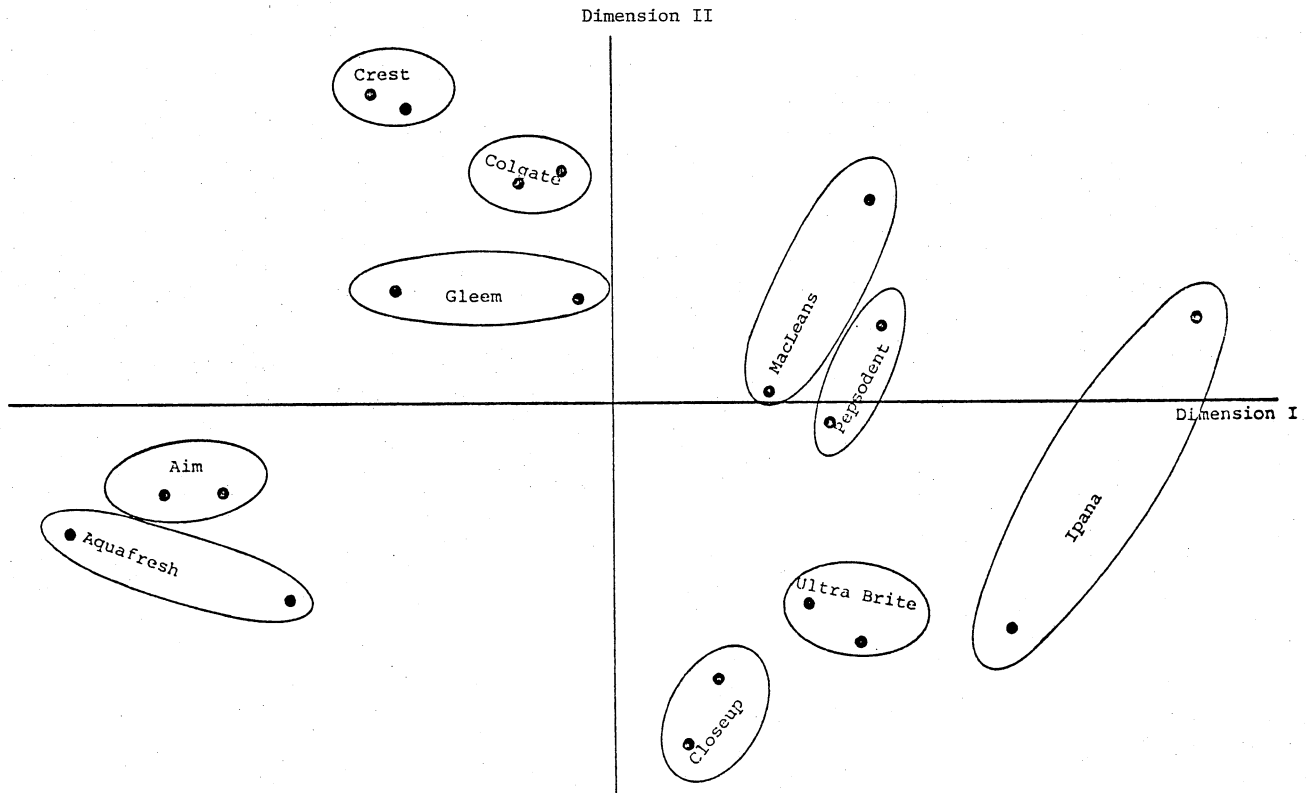

Results and Discussion

The perceptual maps derived from INDSCAL were reasonably consistent over the three week period. The group stimulus configuration is shown in Figure 1. The goodness of fit between periods 1 and 2 was .904 and between periods 2 and 3, it was .762. Distance vector correlations were .746 and .447, respectively. The slightly lower value between weeks 2 and 3 was due largely to variation in the position of Ipana, a brand not familiar to most subjects.

relative importance weights for the spatial dimensions in determining individual utilities for the attributes as they were used by the subject to determine preference. There was weak correlation between these values across the three periods. The correlation between weeks 1 and 2 was .26 and between 2 and 3 was .45.

This result is not surprising. The INDSCAL procedure develops what are in effect individual perceptual maps of the stimulus space. Although the group space may be reasonably consistent between periods there is considerable individual variation in dimensional salience as can be seen from the data in Table 2. In spite of this individual variation, the correlation between individual dimensional saliences is .75 for weeks 1 and 2 and .77 for weeks 2 and 3. In order to correct the utility values derived from LINMAP for the individual variation contained in the INDSCAL results, the utility values must be multiplied by the dimensional saliences. With their correction, the correlation between the adjusted utilities is .61 for weeks 1 and 2 and .74 for weeks 2 and 3. The values of dimensional saliences are shown in Table 2; the LINMAP-generated individual dimension utilities are shown in Table 3; and the adjusted individual dimension utilities are shown in Table 4.

FIGURE 1
Approximate Perceived Positions of Brands
Based on INDSCAL Analysis of Periods I and II

The Spearman rank correlation coefficients for the subject ranked preferences were uniformly high. Between weeks the value ranged between .84 and 1.00 with a mean value of .96. These results indicated subjects were clearly able to perform both the tasks leading to the development of perceptual maps and the preference rank of the stimuli with a high degree of reliability.

The coordinates of the stimulus space and the preference rankings were employed in the LINMAP algorithm to generate

Conclusions

The analysis of perceptions using INDSICAL appears to be reliable as was previously reported (Moinpour, McCullough, and MacLachlan 1976). The increase in the size of the stimulus set from eight to ten did not appear to alter the reliability of the scaling procedure. It was possible that inclusion of additional stimuli might have increased task difficulty and reduced reliability. There is no evidence that this occurred. It should be noted, however, that selection of stimuli can have a noticeable effect on the stability of the map. In this case, Ipana exhibited a much larger variation than Crest; for example, Ipana is not marketed in the area of the study and may not have been familiar to many subjects--it was not used by any. Crest, on the other hand, was the most commonly used product among respondents and exhibited very little temporal movement in the scaling solutions (see Figure 1).

Expressed preferences also appear to be reliable. There is no evidence of significant temporal variation in preference ranking in this study.

The link between perceptions and preference is also quite strong. Although the temporal stability is not as high as might be desired, it is significant and indicates a reasonable consistency in the results.

The major advantage of non-metric analysis is the relative ease of data collection to yield metric output. This type of analysis assumes that sufficient constraint can be placed upon the ordinal data to insure a unique solution. This assumption presents significant problems for perceptual analysis. First, sufficient stimuli must be analyzed to insure adequate constraint. In this case, ten stimuli were used, providing sufficient constraint but requiring subjects to evaluate 45 pairs of products. In spite of this there was no evidence that subjects were unreliable in responding.

The second issue concerns the relationship between the subjects' perceptions and the group space. The INDSICAL

analysis assumes the subjects utilize a common perceptual space and differ in their weighting of the dimensions. The data in Table 5 indicate this may not be true. For some subjects (subject 3, for example) the INDSICAL solution does a poor job of representing their perceptual space. When this occurs, it is not surprising that the results appear to be unreliable. In future analysis, it should be possible to identify subjects with differing perceptions and treat them separately. By doing this, the results should become more reliable.

This study has shown that INDSICAL and LINMAP can be used to jointly analyze preferences and perception. The results appear to be stable over time. Further research is needed to determine if these methods can be used to identify changes in perception and preference to provide a basis for understanding the influence of information and persuasion on the consumer.

TEMPORAL INCONGRUENCY IN CONSUMER BEHAVIOR

Philip E. Hendrix, University of Michigan
Claude R. Martin, Jr., University of Michigan

Abstract

Temporal incongruency is presented as a potentially useful concept in consumer behavior. A consumer who spends more or less time in an activity than he prefers may be labelled temporally incongruent with respect to that activity. Explanations for the presence of temporal incongruency are presented and problems with operationalizing the concept are briefly discussed. Tentative results from empirical analyses suggest the usefulness of the concept.

Introduction

Like money, time may be regarded as a scarce resource which consumers spend. The allocation of time to activities is quite analogous to the allocation of money for goods and services. One faces a (time) budget constraint--say 1,440 minutes per day--which limits the total time spent in all activities. Likewise, there exists a set of activities over which time must be allocated. The analogy is not perfect, however, as time cannot be stored and therefore must be spent as it becomes available. A basic decision facing an individual, then, is the amount of time to spend in alternative activities.

Of course, the allocations of time and money are not independent--in fact, the processes are inextricably related. Consumers spend their money for goods and services which either complement or substitute for their time spent in various activities. For instance, a wide array of products complements the time spent in activities typically regarded as leisure pursuits--witness the significant growth in demand for shoes, apparel, and information brought about by the jogging phenomenon. Other goods and services are purchased as substitutes for the time spent in such activities as home maintenance, e.g., maintenance-free siding, long-life light bulbs, etc., and meal preparation, e.g., convenience foods, microwave ovens, and meals away from home.

Some have argued that because of its scarcity, time may well be the crucial dimension of consumer behavior (Nicosia and Mayer 1976, p. 68). Certainly an increase has occurred in the number of marketing strategies in which time is implicitly reflected: express lanes and expanded hours by retailers; incentives for consumption at "non-peak" times in travel, communication, and utilities; new product offerings aimed at meeting the growing demand for convenience foods and meals away from home; and others. Our limited understanding of the temporal dimension of consumer behavior has undoubtedly impeded the development of marketing strategies consistent with consumers' actual or preferred patterns of time use. While various models of time allocation have been proposed and to varying degrees tested (Arndt and Gronmo 1977, Becker 1965, Chapin 1974, Linder 1970, Morgan et al 1966, Walker and Woods 1976), none is adequately specified. As argued elsewhere (Hendrix 1980), these models are notably deficient in their treatment of subjective needs and characteristics of the individual. The usefulness of specifying subjective as well as objective measures in models of time use was demonstrated for several activities by showing that the time which an individual spends in an activity is positively related to the extent to which the individual enjoys the activity. Such a premise is consistent with the cognitive theory of motivation.

One must question, however, whether this premise holds equally across activities and, for a given activity, whether this premise holds equally across segments of the population. In fact, we doubt that it holds unequivocally across either activities or segments. Rather, we suspect that consumers are less successful in spending the preferred amount of time in some activities than in others and that some consumers are more successful than others in spending the desired amount of time in a given activity. In view of the interdependence of the allocations of time and money, the identification of groups of consumers who spend more or less time in an activity than they prefer would facilitate the development of marketing strategies designed to alleviate this disequilibrium. We will label such consumers temporally incongruent with respect to that activity.

Our thinking was stimulated in part by Hobson and Mann (1974), who developed an overall measure of an individual's well-being by comparing his preferred time expenditures to his actual time expenditures. Consistent with their objective, they examined this relationship on an aggregate basis across activities. We feel that for purposes of marketing planning it is most useful to examine this relationship between time expenditures and preferences at the level of the activity. Analysis at this level permits one to examine the degree of temporal incongruency for each activity and to identify groups of consumers who are temporally incongruent with respect to a given activity, e.g., which consumers spend more or less time in the activity than they prefer.

Finally, we wish to emphasize that our primary objectives are to propose the concept of temporal incongruency and to illustrate its potential usefulness in marketing planning. Issues associated with operationalizing the concept are discussed but by no means resolved. For purposes of demonstration, we present an operationalization using available data and discuss the findings. In so doing, we hope to stimulate much needed research addressing the difficult task of adequately measuring temporal incongruency.

Why Temporal Incongruency Might Exist

Why would an individual spend an amount of time in an activity other than that which he preferred? Why would an individual spend any time in an activity, such as meal preparation, which he dislikes? Conversely, why doesn't an individual spend his or her time only in those activities which he or she most prefers? Various factors affect one's ability to spend time as one might prefer. One of the most significant factors is the frequent incompatibility of immediate and longer term preferences. An individual may be forced to engage in activities which he regards as less preferred in the short run to secure longer-term rewards--work, education, personal care, and home and auto maintenance may represent examples of such activities. Juster (1978) quite aptly labels such behavior "investment"--one foregoes present benefits to obtain future benefits, behavior which is, by definition, investment. We know in fact that investment motives create some temporal incongruency. In response to the question, "Would you say that you do a lot of things that you don't like to do so that your life will be better in the future?" some 50% of the respondents in the ISR Time Use Study described below replied yes or depends.

Other activities require complements which may not be present--for example, weather conducive to the activity; a suitable location; other individuals; and so on. Norms and role orientations may also compel individuals to spend more or less time in an activity than might be expected on the basis of their enjoyment of the activity.

Such factors may singly or collectively suppress the expected congruence between actual and preferred time expenditures. Examining the disparity between the actual and preferred time spent in an activity requires, perhaps obviously, valid measures of each. Less obvious, though, are the difficulties in obtaining such measures.

Data on Time Expenditures

Methods of gathering time expenditure data fall into two major categories: self report and observations by a second party. The latter is subject to its own limitations (Wells and LoSciuto 1966) and, due to cost, is practical in only a limited number of situations. There are a number of approaches to eliciting time use information directly from respondents. Perhaps the most prevalent approach has required the respondent to estimate his or her "typical" time expenditures over some limited period, e.g., a week (Hawes 1977), or frequency of participation over an extended period of time. The accuracy of such estimates has been questioned, however, by recent validity studies (Robinson 1977; forthcoming). Though it too relies on self report, the time diary method is generally regarded as the most accurate source of time use data.

The time diary is an instrument in which the respondent records (either synchronously or shortly thereafter) the activities in which he or she engages over the period of interest, usually 24 hours. Typically recorded for each event are beginning and ending times, concurrent activities (e.g., watching television while eating lunch), location-and others present. Figure 1 shows a few of the entries corresponding to more or less discrete events in a hypothetical time diary containing the elements mentioned above.

A time budget showing the allocation of time, say 24 hours, to various activities can be constructed by summing the time devoted to each activity during the day. Hence, the hypothetical respondent whose diary appears in Figure 1 spent 8 of his 24 hours in sleep. Aggregates of the time devoted to other activities may be derived similarly. These measures complement the fine-grained data found within the diary itself.

Since the diary collects data for a fairly short period of time, estimates at the individual level of time spent in activities in which individuals infrequently engage are subject to wide variation. For instance, an activity in which a respondent engages once a week only has a probability of 52/365 of showing up in his time diary for a given day. One way to reduce this variance in estimates of an individual's time expenditures is to collect a larger number of time dairies.

The analyses in this paper utilize a subset of data collected by the Survey Research Center of the Institute for Social Research, University of Michigan, in a major study of time use among Americans in 1975-1976. The national probability sample consisted of respondents, 18 years of age and older, and their spouses (1,519 and 887 respectively for a total of 2,406 individuals). The design specified that each individual provide on four separate occasions, approximately three months apart, a time diary for the previous 24 hour period. Considerable attitudinal, behavioral, and demographic data pertinent to the use of time were also obtained across the four waves of the study. In addition to controlling for seasonal variations in time use, the design avoided the bias due to differences between weekdays and weekend by collecting time diaries from each individual for two weekdays, a Saturday, and a Sunday. This complex design yielded the most reliable, representative measures of time use available for a national sample. A time budget containing estimates of the number of minutes spent in each of some 89 activities during a given week was derived for each individual from his or her time diaries.

Measures of Preferences

As suggested earlier, there exists a set of activities over which time must be allocated. Thus, one might regard activities as objects of choice capable (to varying degrees) of satisfying an individual's needs. Given an individual's hierarchy of needs, their saliences, and subjective reports of the extent to which various activities satisfy those needs, relatively preferred activities may be determined, perhaps relying on an approach analogous to multi-attribute modelling of product preferences. Though no one to our knowledge has used such an extensive approach, considerable information could be gained pertinent to preferences for alternative activities as well as underlying attributes of activities which determine their ranking.

FIGURE 1

SAMPLE OF EVENTS FROM
A TYPICAL TIME DIARY

TIME		PRIMARY ACTIVITY	SECONDARY ACTIVITY	LOCATION	OTHERS PRESENT
BEGAN	ENDED				
00:00	06:30	Slept	----	Home	Alone
06:30	06:45	Washed	----	Home	Alone
06:45	07:00	Dressed	Talked with Wife	Home	Wife
07:00	07:30	Ate Breakfast	Watched TV	Home	Wife, Child
07:30	07:55	Drove to Work	Listened to Radio	Street	Alone
o	o	o	o	o	o
o	o	o	o	o	o
o	o	o	o	o	o
22:20	22:30	Dressed for Bed	----	Home	Alone
22:30	24:00	Slept	----	Home	Alone

An alternative approach is to ask the respondent directly to articulate his or her preferences for activities, e.g., in which activities would the respondent prefer to spend his or her time. Such an approach assumes, of course, that the respondent can array his preferences. Moreover, it ignores the potential effect of situational factors on preferences--for example, the hierarchy for an evening following an 8 hour day at work is likely to differ from the one for a Saturday evening. Though simpler, this approach does not permit one to determine why one activity is preferred over another. One is forced to regard these preference measures as exogenous, which may be unacceptable for certain analytical purposes.

In using this direct approach, problems with interpretation may arise unless one employs an unambiguous term "descriptive of a person's affective state" (Jones and Pierce 1977, p. 298). For instance, a set of activities may be arrayed quite differently if one is asked to rank them from "most satisfying" to "least satisfying" versus from "most enjoyable" to "least enjoyable." Respondents may interpret the first scale to allow for intrinsic/extrinsic, concomitant/non-concomitant reinforcement corresponding to an activity while the second scale is likely to be interpreted as allowing only for intrinsic, concomitant reinforcement.

The point of this brief discussion is that alternative approaches to measuring activity preferences exist. Unfortunately, we know little about the comparative validity of measures obtained from any one of these approaches. Respondents in the ISR Time Use Study were asked to rate some 22 activities on a scale of zero (dislike a great deal) to ten (enjoy a great deal). To improve the comparability of these ratings across respondents, we standardized the scores by respondent, e.g., for each respondent, his or her ratings of the 22 activities were used to compute a mean and standard deviation which were then used to convert the 22 "raw scores" to standardized scores. Thus, negative scores reflect relatively less enjoyable activities, and vice versa, in the individual's subjective estimation.

Determining the Extent of Temporal Incongruency With Respect to an Activity

In the sections which follow, the reader should keep in mind that our data only permits us to infer the presence of temporal incongruency. That is, we do not know that a respondent would prefer to spend some amount of his time in the activity other than that which he is spending. Nevertheless, we think it reasonable to suspect that temporal incongruency exists if an individual is spending large amounts of time in an activity regarded as relatively unenjoyable, or a small amount of time in an activity regarded as relatively enjoyable.

Collapsing the time expenditure and enjoyment measures into three subsets of equal numbers and cross-tabulating the two trichotomies resulted in Table 1 for the activity of meal preparation. Approximately 58% of the sample falls in the off-diagonal cells of Table 1, tentatively suggesting the presence of temporal incongruency. Nearly 28% (above the main diagonal) appears to be spending less time than preferred, while 30% (below the main diagonal) appears to be spending more time than preferred. The latter proportions provide some insight into the nature of temporal incongruency which exists with respect to the activity.

Characterizing Temporally Incongruent Segments

Methodology

One approach to disaggregating a sample into segments in which the relationship between y and x differs is an infrequently used variant of the AID algorithm called AID

TABLE 1

Cross Classification of Time by Enjoyment for Meal Preparation

Minutes/Week	Enjoyment of Meal Preparation			
	Less Enjoyable	Neutral	More Enjoyable	
0-60	15.1%	10.5%	6.6%	32.2%
61-360	11.8%	11.4%	10.9%	34.1%
361 and up	6.5%	11.4%	15.8%	33.7%
	33.3%	33.3%	33.4%	100%

covariance analysis (Sonquist et al 1978; Rao et al 1976). Typically, AID is employed to sequentially partition a sample into mutually exclusive subgroups so as to maximize between group variation (or equivalently, minimize error sum of squares) with respect to the mean levels of some dependent variable y. In the covariance mode, AID uses mean levels of y and a covariate x to disaggregate the sample. The analysis begins with a simple regression of y on x--here, the time spent in the activity on the corresponding measure of enjoyment. The initial error sum of squares is that left unexplained by the regression. The algorithm then examines subgroup regressions of y on x within alternative dichotomous partitions of the original group--say, within groups defined by age, sex, income, or other plausible bases. The sample is split on that predictor which maximally reduces error variation and satisfies other user specified constraints, e.g., minimum group size. The partitioning is repeated for subgroups, stopping when the variance reduction and minimum groups size criteria can no longer be satisfied.

The results of the AID covariance analysis for meal preparation are presented in Figure 2. Again, the dependent variable is the time (number of minutes per week) spent in the activity while the covariate is the level of enjoyment corresponding to the activity. The predictors--bases upon which the sample may be partitioned--included both demographics and psychographics which may be expected to moderate the relationship between time and enjoyment for reasons discussed earlier.

Results

The AID covariance analysis provides some insight into the factors which may generate temporal incongruency with respect to meal preparation. Segment 6, for example, comprised of single, non-employed women, spends less time in cooking on average but enjoys the activity more than does the overall segment of women. Segment 11, on the other hand, spends a relatively large amount of time in an activity which they regard as relatively enjoyable.

Using the Results

We stress once again that our data permit us to only indirectly examine temporal incongruency. Though subject to this and other caveats noted throughout the paper, the findings from the above analyses will serve as the vehicle for suggesting the implications of temporal incongruency.

The extent and nature of temporal incongruency with respect to an activity such as meal preparation is a useful barometer of probable shifts in future demand. For example, the respondents who spend more time than preferred in preparing meals are likely to be responsive to microwave ovens, convenience foods, meals away from home, and other goods and services which allow them to reduce this time expenditure. As this segment grows, the demand for time-saving products is likely to intensify. Conversely, the respondents who are spending less time cooking than desired may continue to demand time-intensive foods and modes of preparation and ignore time saving goods and services.

Uncovering the reasons for this temporal incongruency is also useful. From Figure 2, it appears as though women who are employed full-time enjoy meal preparation nearly as much as all women on average and yet spend nearly 200 minutes per week less. Has the time devoted to employment reduced the time which these women have available to spend in the activity? Which activities, if any, provide the reinforcement which previously resulted from cooking? Can these considerations be incorporated into product development and promotional strategies?

Summary

The process by which consumers spend their time is not well understood. Neither is the interdependence between the allocation of time and the allocation of money (or, equivalently, the interdependence between the selection of activities and the selection of goods and services) fully appreciated. We hope that this discussion of the concept of temporal incongruency will stimulate research which improves our understanding of these important facets of consumer behavior.

Abstract

The "future," having no concrete basis in reality, is best conceived as part of an individual's thoughts or imagination. Many theoretical frameworks for studying consumer behavior incorporate some aspect of how consumers envision future events, yet little theoretical or empirical work has addressed this concept directly. This paper reviews several topics which implicitly include a future perception concept and suggests how these and other areas of study could benefit from models which incorporate the concept explicitly. The potential dimensionality of such a concept is reviewed in the context of a typology of futurizing styles.

Introduction

Research on time and consumer behavior has focused mainly on the time allocation process (Wilson and Holman 1980). This "economic" perspective on time is, however, only one of several worthy of attention by consumer behavior researchers (Settle 1980). Although the literature contains numerous examples of the "subjective" approaches (see Jacoby, Szybillo, and Berning 1976) relatively few works directly address how consumer decision making is affected by individuals' subjective experiences of time. (An exception is Settle, Alreck, and Glasheen 1978.) The topic of the subjective experience of time is an important one for consumer behavior researchers, however. Just as the concept of "perceived risk" has expanded the ability of researchers to explain consumer behavior toward risky products or services, so may study of the perception of time enable a more thorough explanation of time budgeting. Consumers who perceive units of time differently may plan different activities for otherwise identical time periods. Thus, perception of time may be a meaningful basis for market segmentation to the extent that consumer decision making is affected by time perception.

While it seems that consumer behavior researchers have neglected an important facet of human behavior, in fact that neglect is more apparent than real. As Hawes pointed out (1980) many of the global models of buyer behavior incorporate some references to consumers' experience or perception of time. Furthermore, one aspect of time perception, the conceptualization or imagination of the future, is embedded in several of the explanations of buyer behavior employed by past researchers. If such a concept exists, if it impacts upon consumer behavior, and if it has remained unmeasured, even "hidden" in previous studies, then there is a potential benefit to be gained by scrutinizing it and explicitly investigating its impact. The purposes of this paper are to examine the concept of the imagination of the future, to review some of the consumer behavior topics which implicitly incorporate the concept, and to suggest the dimensionality of the concept.

Imagining the Future

Before discussing the potential impact that conceptualizations of the future have on consumer behavior, it is first necessary to define the concept and to briefly trace its

history in the literature. That is the purpose of the first part of this paper.

A basic premise underlying the paper is that the future, since it can never be experienced directly, is wholly imaginary. This existential position is compatible with Lewin's ahistorical approach (see Kassarian 1973) to cognitive processes and leads to the conclusion that time itself has relevance only as the individual structures it into something meaningful. The future is no more or no less "real" to the individual than the past as both reside equally in the imagination, whether of remembered or of anticipated events (Lewin 1936).

The two major categories of events which enter into an individual's life space and impact upon that individual (within Lewin's theory) are things in the environment and things in the person's mind (Lewin 1951). As the latter may consist of current perceptions or of imaginary events (from the past or the future), it follows that the future holds a very important place in the life space of the individual.

Such an importance of the future is not found in other conceptualizations of human behavior. Freudian psychology, for example asserts that the past determines the present with imagination of the future (should it occur at all) being dominated by recollections of past events. Likewise, Marxian social theory sees the present and the future being determined rather irrevocably by past events (although it is the promise of a better future which serves as the motivating force in overturning capitalism for example).

Some researchers have attempted to deal with aspects of the imagination of the future. One group has looked at the length of one's future time perspective (how far into the future one normally thinks) and how that relates to a variety of other behaviors (e.g., Heimberg 1963; Bauer and Gillies 1972; Lamm, Schmidt, and Trommsdorff 1976). Another approach has been to study the physiopsychological bases of time perception (e.g., Michon 1975). Both of these approaches have measured time objectively with mechanical recording devices like timepieces or calendars, or in reference to such devices, which may not be how time is always perceived (especially when the individual is in a heightened emotional state). For example, there is evidence that the existence of a well-developed concept of the future is a key element in the psychological adjustment of terminally-ill patients, even when that future, when measured in objective terms, is not likely to be realizable (Susman 1980).

What is most important about one's imagination of the future is how that imagination or orientation to the future affects current behavior. (It is equally important to measure one's orientation to the past, but that is not covered here.) The concept of future imagination has appeared (albeit implicitly) in a number of past explanations given for human (and consumer) behavior. A review of several of these further illustrates the importance of the concept.

Aspects of Human Behavior Incorporating the Concept of Future Orientation

Cultural Influence

Culture incorporates time perception in the verb structure of the language of the culture. The Whorfian linguistic relativity hypothesis, that one is only able to think in

¹This paper was prepared while the author was a member of the Marketing Department, The Pennsylvania State University, University Park, PA.

the terms provided by one's language (Whorf 1956), would lead to the conclusion that if the verbs of one's language include past, present, and future tense, then one structures time into these categories. If one's language includes verb tenses which do not contain a category for events and behaviors which have not yet occurred (Arabic is one example), then one will not speak (or think) of the phenomenon of the future the same way as one who speaks and thinks in Standard American English (which does include a future tense). Furthermore, there is the possibility that one language may include verb forms which create new conceptualizations of time or span time dimensions (from the perspective of one language) making temporal translations from one language to the other virtually impossible. (See Whorf 1956, for a discussion of Hopi verb structures with these characteristics, pp. 143-5).

This is an important problem, and potential source of error in data, when one attempts research trans-culturally. For example, in the United States, approximately eighty percent of all blacks speak a language referred to as "Black English" (Baratz and Shuy 1969 quoted in Dillard 1972, p. 229), and "[i]n the system of its verbs, Black English reveals the greatest difference from white American dialects..." (Dillard 1972, p. 40). The problem is further compounded because Black English and Standard American English resemble one another superficially, sharing a great number of words. In fact the tendency in the past has been to characterize the language of most blacks as a "substandard" form of Standard American English, which it is not (Dillard 1972, p. 39-70). Thus research on blacks which does not incorporate the notions of time (and the future) inherent in the tenses of Black English risks interjecting an uncontrolled and perhaps unconscious source of bias.

The point is that by the very language used to communicate with subjects (or with members of a target audience, for example) the person forming messages imposes a concept of time (and futurity) inherent in the language used. Even if the respondent can translate from one language to another, there is a potential for misunderstanding unless the respondent is truly multi-lingual and thinks in the time categories used by the initiator of messages. (This potential for misunderstanding apparently exists even with languages which are "linguistically close" as with French and German.²)

Sociological Influence

An important component of the "sociology of consumption" is the set of cultural values held by consumer groups (Nicosia and Mayer 1976). The work by Rokeach (1973) has established the impact of values upon human behavior and their usefulness in explaining buyer behavior has also been documented (e.g., Vinson, Munson, and Nakanishi 1977; Vinson, Scott, and Lamont 1977). What has not been explicitly recognized is the implicit temporal quality of values as operationalized by Rokeach and those who use his work as a foundation.

A key element in Rokeach's concept of values is the subset referred to as "terminal values." As pointed out by Vinson, Munson, and Nakanishi, Rokeach thought of terminal values as descriptive of "the individual's desired end-state of existence..." (1977, p. 247). In order to respond to the Value Survey developed by Rokeach, a subject would need to evoke his/her ideal image of the future. Thus the concept operationally requires that a subject has formulated some concept of the future and that he/she describe it using the Value Survey.

Carman (1978) may have recognized the temporal dimension of values, although this is not discussed in his paper. Carman formulated a model relating values, life styles and consumption. One concept in his model was terminal values, another was time use activities. Carman, in effect, has stated the relationship between perception of the future and time use posited at the beginning of the current paper and has extended the relationships to life styles and other types of buyer behavior.

A subset of personal values influencing the perception of the future is the impact of religious beliefs. Religious groups in the United States have noticeably different degrees of belief in a spiritual afterlife and this apparently affects the time allocation processes of members (Azzi and Ehrenberg 1975). Thus the individual who believes that a reward in the afterlife is predicated upon laboring to "increase his talents to the greater glory of God" (Green 1972, p. 412) is likely to behave quite differently in the present than one who does not believe in an afterlife or who does not believe that efforts during one's life affect one's destiny after death. Green (1972) has done an excellent job along these lines of contrasting the temporal attitudes of Negro subcultures with those adhering to the ideals of the Protestant Ethic, a contrast which finds its basis in religious beliefs.

An even sharper contrast is found between the linear concepts of time found in most "western" religions and the non-linear concepts of some "eastern" religions, notably Buddhism and Hinduism. These differences may lead to different beliefs for example about the importance of one's death, about the significance of units of time for planning purposes, and more importantly for consumer behavior researchers may make possible an eastern acceptance of one's social status that is not feasible in western cultures (Olcott 1944; Pocock 1976).

The religious beliefs held by groups within society may predispose individuals against even speculating on the future. The argument is that as everything is under God's control, by trying to envision what will come, one is trying to "second-guess" God. Forecasting is prohibited as it presumes a knowledge that is God's alone. An example of this was reported by Eickelman (1977) who described the Muslim influence upon Moroccan tribesmen, but such an orientation toward planning and forecasting is undoubtedly present to some degree in all groups which believe in predestination.

If one were to use religious teachings (or beliefs) about the future as covariates in research, the differences in future orientation could possibly be measured and controlled in analysis. Otherwise such aspects of time and future orientation remain as random error in analyses of heterogeneous groups.

Psychological Influence

Attribution theory, the study of how individuals perceive the causes of behavior, contains a large temporal component. This relationship was pointed out by Kelley: "Implicit in the covariation principle is the important and little investigated problem of the exact temporal relations assumed to exist between a cause and its effect" (1973, p. 109). A typology of causality which defines the possible temporal relationships between cause and effect was developed by Evered (1976). Evered identified three primary types of causes: antecedent causality (behavior occurs because of some event that preceded it in time); concurrent causality (behavior occurs because of some event that occurs at the same time); and prospective causality (behavior occurs because of some event that has not yet occurred but should occur in the future).

When attributions deal with "expectations" the notion of the nature of the causality of the future is invoked.

² Anecdotal evidence supplied by Gerard M. Langneau, personal communication, October 1978.

Belief that the future is based upon events occurring in the past, a major premise of most forecasting techniques, involves a concept of antecedent causality. One expects a future that is similar, under similar conditions, to events that one has observed in the past.

Using a concept of concurrent causality would predispose an individual to expect that events occurring at a future point in time will be a function of whatever else occurs at that point in time. This is a Gestaltic notion of events, very similar to Lewin's explanation of behavior (1951). One does not expect any particular event to occur but could envision a number of alternative scenarios.

A belief that an individual is able to shape future events by the actions taken in the present is an explicit belief in prospective causality. One expects what one has planned to occur in the future. The future is, therefore, foreseeable and manipulable to some extent. (The concept of the "self-fulfilling prophesy" fits nicely within this notion of causality.)

These three types of causality produce different conceptualizations of the term "expectations," and yet the type of causality used by individuals has been empirically investigated only rarely. Mizerski and Green (1978) studied causal schemata, but ignored the temporal dimensions of that causality. However, Mizerski and Green did determine that one's causal schema was related to other cognitive processes, suggesting that a clarification of temporality in causality could produce even stronger relationships among variables.

There are also concepts of the future embedded in some of the personality traits studied in the past. Some of these are listed below along with a brief discussion of the aspect of future perception captured by the trait.

Dogmatism. The highly dogmatic individual is resistant to change preferring familiarity in events. This suggests that the high dogmatic desires a future that closely resembles the present and a present that closely resembles the past.

Need for Change. The individual with a high need for change gets bored by repetitive tasks and environments. Unlike the high dogmatic, an individual with a need for change seeks a future that is unlike what has yet been experienced.

Need for Order. The person with a high need for order can express it either through spatial ordering (keeping physical objects neat) or through temporal ordering (having things well-planned). When the ordering is expressed temporally, the individual hopes that the transitions into the future take place as planned and without discontinuities.

Locus of Control. A highly internal person believes that events occur due to his or her own intervention. This individual sees the future as both predictable and alterable, depending on what he or she decides to do. The highly external individual, by contrast, sees the future as subject to control by forces other than those of the individual.

Creativity. The person who is highly creative has an active imagination and is thus likely to be capable of producing many different scenarios of the future when asked to do so. This individual may also delight in envisioning futures that have not been conjectured before.

Deferred versus Immediate Gratification. A person who is able to defer gratifications implicitly believes in the existence of a future in which those pleasures may be enjoyed. A person who opts for immediate gratification may feel that the future is so uncertain that one should take life's pleasures as they are presented.

While it would be theoretically possible to partition the above traits into a time component and all other components, it is unlikely that such an action would materially affect the research which has attempted to relate personality to consumer behavior. As pointed out by Kassarian and Sheffett (1975), that body of research has been notably poor in isolating strong relationships and explaining much of the variance in the data. A more fruitful approach is the one taken by Settle, Alreck, and Glasheen (1978) who developed an instrument to measure time perception directly, treating it as an individual differences variable. What the above review illustrates is the pervasiveness of time (and especially future) dimensions in conceptualizations of human behavior.

The Dimensionality of Future Imagery

It is now possible to construct a theoretical statement of the dimensionality of perceptions of the future. From this statement one ought to be able to construct hypothetical types of ways of imagining the future. These dimensions are discussed next.

First, it is probably essential that any discussion of future dimensionality be limited to one cultural or linguistic group, unless a sufficient similarity in verb structures can be demonstrated. Unless the categories used to conceptualize time are essentially the same, one risks enormous errors in interpretation.³

From religious beliefs (and some personality traits) is the notion of the extent to which the future is predictable by man. Related to this, but slightly different is the degree to which an individual has control over the future, or whether that is under God's discretion alone.

Concepts of causality lead to envisioning the nature of causality itself. Next are a series of dimensions related to change: what is the rate of change between the present and the future and how does that differ from the rate of change in the past; is change valued and if not, is it disruptive (of individuals or of society in general). Finally is the concept of the number of images one has of the future (permitting this number to equal zero perhaps when the language does not possess a future tense).

An application of this theoretical dimensionality can illustrate its utility. The work of Evered (1973) is a useful vehicle, as Evered's purpose was to identify the characteristic way individuals had of thinking about the future. Using an exhaustive procedure (including content analyses of samples of writing, responses to personality tests, and performance measures), Evered, through a phenomenological analysis, derived three futurizing styles. He called these "producer," "performer," and "prospector," (although "performer" was later renamed "participant" to more clearly reflect the intra-organizational characteristics of that type of individual). Each of these three styles is presented in Table 1 and is characterized in terms of the dimensions discussed above.

As can be seen from Table 1, the producer sees a single-imagined future that is predictable because of its similarity to the present (and the past). The individual does not have control over the future since events set in motion in the past will cause those events which are to occur. Change, when it occurs is disruptive and not valued.

The participant, like the producer has one image of a predictable future, but differs from the producer in that the

³ An illustration of cultural/linguistic differences in the dimensionality of numeric measuring systems between Liberians and Americans can be found in Cole et al. (1971).

Dimensions of Future Image	Futurizing Style		
	Producer	Participant	Prospector
Is the future predictable?	yes	yes	no
Does the individual have control over the future?	no	yes	no
What is the relationship to the future and the present?	identical or highly similar	linear but positive slope	discontinuous
Nature of causality	antecedent	prospective	concurrent
Rate of change in the future	slow or none	constant	accelerating
Is change valued?	no	yes	yes
Is change disruptive?	yes	no	no
Number of images of the future	one	one	many

^aTypes were described originally in Evered (1973).

future is different from the past. Change is valued if that change is orderly (and hence predictable). The individual has a dynamic impact upon the future, being instrumental in its design.

The prospector has traits in common with both the producer and the participant. Like the producer, the prospector does not see the individual as having control over the future; like the participant, the prospector sees a future that is different from the present. The prospector, however, is unwilling to predict the future as he/she envisions change as discontinuous with the present, and can therefore predict not one but many future scenarios. Change is not disruptive for the prospector; it is sought-out and valued.

Other hypothetical futurizing types could be generated, but these three have the advantage of being derived from observations of subjects (who were M.B.A. students at U.C.L.A.). Other work needs to identify whether these three types exhaust the universe of realized types, and to determine the distribution of these three in other populations. An instrument to operationalize the measurement of these three was developed (Evered, Reilly, Holman 1976), but that instrument has not been fully validated to date.

Theory Building Using the Concept of Future Imagery

This paper has suggested that unexplained sources of variances in buyer behavior could be decreased by incorporating the concept of consumers' images of the future as a variable in analyses. This means that the concept needs to be included explicitly in models of consumer behavior, where in the past it was subsumed in other concepts (some of which have been discussed here). The following list provides suggestions for topics which might benefit from such a practice and also raises some other issues concerning the concept itself.⁴

- To what extent are budgeting activities (whether of time, energy, or money) affected by an "inflation psychology," which is nothing more than a particular scenario of the future?

- How are investment patterns and durable goods purchases affected by one's futurizing style and by the nature of the future one envisions?
- Dissatisfaction often results when one is not able to realize the future one had envisioned. Do consumers with different ways of conceptualizing the future have different tolerance levels for this type of disappointment?
- What is the impact upon buyer-seller interactions when each has a different style of conceptualizing the future?
- How is risk perceived differently by those with different images of the future?
- Is one's style of conceptualizing the future affected by the aging process? Are age cohorts more likely to share future scenarios or is the future scenario independent of one's own age?
- Is futurizing style situationally-dependent or does it span situations?
- What are the cognitive processes underlying one's futurizing style?
- Aside from linguistic differences, is there a sense of time and the future that spans cultures? If so, what are its dimensions?
- Is the concept of the future likely to be of less importance in non-deliberative decision making than for planned purchases?

Obviously, a first step in investigating these and other questions is construction of an instrument to operationalize the concept of future imagery. The FAST instrument developed by Settle, Alreck, and Glasheen (1978) measures time orientation and has been extensively validated. Although it includes the future as one dimension, it was not designed for the work indicated here. Likewise, Heimberg's instrument (1963) measures the length of time one thinks into the future and is also not satisfactory. Constructing an instrument which does measure futurizing style is another area needing attention.

Conclusion

This paper has defined a concept of "future imagery" and identified how it has existed as an implicit concept in past research. Rarely has the concept been measured directly in the consumer behavior literature and thus any effect due to its influence remains as unexplained variance in analyses. The dimensionality of the concept was suggested and illustrated through presentation of a typology of futurizing styles developed previously. Suggestions for research questions linking the concept of future imagination to buyer behavior were provided.

TIME AND CONSUMER BEHAVIOR

Wesley J. Johnston, The Ohio State University

Abstract

The use and expenditure of time is inextricably linked to consumer behavior. As Jacoby et. al (1977) point out "Acquisition and consumption of both products and information regarding products are not cross-sectional events of short and unvarying duration." It has even been proposed that time may be the most important variable in consumer behavior (Nicosia and Mayer 1976). Our state of knowledge, however, finds us caught in an interesting anomaly. On the one side, the time dimension of consumer behavior is viewed as just beginning to emerge as a major variable of study, as three articles reviewed here indicate. On the other side, however, time has been implicitly and explicitly incorporated into consumer behavior theory and marketing strategies for quite some time. This article first reviews the history of the incorporation of time into consumer behavior theory and marketing strategies and then reviews the three articles concerned with "Perception of Time and Consumer Behavior".

Introduction

The treatment of time as a variable of importance in understanding consumer behavior has been accelerating. It is almost as if the fact that time exists and must affect consumer behavior has just been "discovered". Perhaps this is part of a larger awakening to the pervasiveness of time. As Voss and Blackwell (1979) note: "The importance of time in all aspects of American life has become a recurrent theme in the academic literature of the seventies. Interest has been cross-disciplinary."

The explicit treatment of time as a variable in consumer behavior has been sporadic. However, the implicit treatment of time has a much broader base. Many aspects of consumer behavior change over time: attitudes, perceptions, motives and values, lifestyles, and the political, cultural, technological environment. Most of the marketing literature has been directed at understanding what causes these changes and not the amount of time necessary for such changes to take place or the rate at which such changes occur. In addition to time's implicit involvement in consumer behavior, many consumer behavior concepts are explicitly dependent upon the use of a time dimension. Brand loyalty, for instance, is often operationalized as purchase patterns over time. The product life cycle examines distinct stages in the sales of a product over time. Concepts in innovation diffusion are also heavily dependent upon time. In the consumer adoption process, the consumer is seen as going through a series of stages of acceptance in adapting a new product and adopter categorization is made on the basis of relative time of adoption (i.e., innovators vs. laggards). Advertising wearout needs time to occur. Convenience shopping and specialty goods are classified according to the time and effort expended in their acquisition.

Most models of consumer behavior, especially those of an information processing type, consider a time element. Kotler (1972) in a "logical" model of buyer behavior depicts the buyer as problem solver deciding on product, brand style ... time, price, and way to pay. The Howard and Sheth (1968) theory of buyer behavior focuses on the task of explaining brand-choice behavior over

time rather than purchase frequency or purchase quantity. Bettman's (1979) information processing theory of consumer choice not only depicts consumer behavior occurring over time but explicitly acknowledges the effects time pressure can have on information processing and choice. Linear learning and Markov models of brand choice also incorporate a time factor.

It can be seen that time is integrally involved in consumer behavior and has been both implicitly and explicitly integrated in many models and concepts. Thus, "Acquisition and consumption of both products and information regarding products ... are dynamic processes that occur over time and that may involve different spans of time from one occasion and one individual to another (Jacoby, et. al. 1977)." The understanding of how the time dimension affects consumer behavior can lead to improved strategies for marketers.

Marketing managers are basically involved in decisions of two types: market segmentation and marketing/mix formulation. An understanding of the time dimension as it affects consumer behavior can improve decisions of both types. Changes in consumer segments over time have been clearly established by research in marketing. These include changes in consumer demographics, benefits sought by segments and perceptual spaces for products.

Engel et. al. (1978) provide a discussion of changes in consumer demographics and how these will affect the markets for goods and services. The two most obvious are the dramatic age changes in the population (increases in the over 65 geriatric market and 25-34 baby boom primary home buyers market and decrease in the teenage market) and the divorce, separation tendency creating many single parent households. These demographic trends translate to many new opportunities for marketers as well as the need to change current offerings.

Calontone and Sawyer (1978) discovered that while market segments defined by relative importance of product attributes (benefit segments) remained relatively stable in size, individual households changed segments frequently. This research was conducted over a two year time period. They concluded by indicating the need for more longitudinal research to monitor the benefits sought by individual consumers to help explain why and how such changes occur.

Moinpour et. al. (1976) employed multidimensional scaling techniques in a longitudinal experiment as an approach to investigate attitude processes. The study demonstrated that MDS techniques were appropriate for monitoring dynamic changes in perception caused by persuasive communications over time. Differential impact of message characteristics were also noted. The fact that perception changes over time could have perhaps been taken for granted but discovering a way to measure those changes, was an important contribution to understanding consumer behavior and aiding marketing management.

As the understanding of the influence of time on consumer behavior improves, the ability to incorporate this dimension into the modeling of market response models will increase. The purpose of a market response model is to relate sales or market share of a firm to its advertising,

price, promotion, distribution and/or other decision variables. Several studies currently exist which lead the way to the incorporation of time into marketing mix strategies.

Mickwitz (1959) discovered that advertising elasticity was highest at the growth stage of a product due to the need to create increased product awareness and lowest during maturity. Elasticities increased slightly through the saturation and decline stages of the product life cycle. Mickwitz also believed time-varying elasticities would exist for price, service, product quality, and packaging.

Voss and Blackwell (1979) hypothesize that as the value of time changes and the desire for more intensive time experiences increases, new product opportunities will develop especially among consumers with a serious leisure time scarcity. Those seeking physical fitness through recreation may switch from golf, a heavy time-investment sport, to tennis or raquetball. Thus, product or service redesign may be needed as time value changes. Voss and Blackwell also indicate the need for convenience or "time-saving" products. Appliances, such as microwave ovens and dishwashers, and services, such as lawn care, may be experiencing rapid growths in sales as a result of consumers buying increased discretionary time.

Mahajan et. al. (1980) demonstrate the need for feedback approaches to develop self-adaptive market response models. They indicate that the notion of market response varying over time was not new and actually well grounded in marketing literature. Their approach provides time-varying coefficients of advertising retention using Lydia E. Pinkham data. They conclude by noting that the use of such popular approaches of parameter estimation as least squares, Box-Jenkins, and other econometric techniques assume stability of coefficients over time and this may lead to a market response model insensitive to the reality of market conditions.

Contributions of the Articles Concerned With Perception of Time and Consumer Behavior¹

This section deals with the three articles presented in the session on the perception of time and consumer behavior. The article by McCullough, MacLachlan and Moinpour, "Temporal Links Between Preference and Perceptions" provides the only treatment of time from a longitudinal perspective of the three papers examined here. As such, I feel it examines the "main" effects of time on consumer behavior. The study shows that INDSCAL (Carroll and Chang 1970) and LINMAP (Srinivasan and Shocker 1973) can be used to jointly analyze preferences and perceptions and, as the authors argue, the results appear to be stable over time. This perception on the part of the authors is questionable, however. Do correlations in the range of .6-.7 truly show stability over time? One could argue just the opposite, especially since the interval between retesting does not permit much in the way of relevant intervening experience to occur. This position could perhaps be strengthened by citing generally acceptable levels of reliability in test-retest results at a one week interval. Another issue here is that the authors seem to feel inclusion of the brand "Ipana" reduced the stability observed in their analysis. Would it not be possible to delete this brand and rerun the experiment? The authors may then have support for their statement that selection of stimuli can affect reliability. A more general criticism of this paper deals

¹This section contains some comments made by anonymous reviewers as well as my own.

with the somewhat mechanical approach to the problem and the reporting of the results. The inability to control for the respondents' prior familiarity with the brands is a problem. The explanation given for the choice of toothpaste as the product category is only that this was the same as used in a previous study. While this may be valid because of the attempt to extend the earlier study, why not indicate the reason for choosing toothpaste as reported in the original study? Two additional brands were added to this study and in my opinion one should have been deleted. The authors report the "Ipana" is not marketed in the area where the study was conducted. Another important aspect of the paper is the use of CMATCH. This is a conservative procedure since rotation of the two spaces to maximal congruence precedes computation of correlational and proximity measures. CMATCH also uses two measures of congruence for reasons which are appropriate in calculating relationships between utilities and attribute weights.

Overall, this paper does accomplish its objectives of linking preference and perception temporally and provides direction for continued research in that direction. The authors are to be commended for this pioneering work.

The article by Hendrix and Martin, "Temporal Incongruity in Consumer Behavior" provides an interesting concept that can perhaps explain some of the variance in consumer behavior. Temporal incongruity, unfortunately, seems to be an unavoidable fact of life. While temporal incongruity can be improved for some situations such as cooking by the use of microwave ovens, instant foods, or fast food restaurants for those who want to spend less time on this activity, and by gourmet cookbooks, classes on cooking at universities, and all original ingredients for those who want to spend more time cooking, some activities still seem to resist temporal improvement; education is one example. The data analysis presented here is exploratory and indicates that further work needs to be done in modeling the relationship between time spent on and enjoyment derived from an activity. One problem that exists here is the ability of some individuals to be multi-phasic. The ability to do two or more things at one time such as drive to work and listen to the radio, watch television and write letters or balance the check book, ride the bus to school and do one's homework. Some people are capable of accomplishing three, four or even more activities at the same time. Modeling time incongruity for this type of individual presents several problems:

- A time budget will overstate the amount of time of activity for a multi-phasic person.
- How does one measure time per activity when two or more activities are carried on at the same time?
- Perhaps time incongruity - performing an activity longer than one wants to - leads to multi-phasic behavior in order to reduce mental attention to the incongruent activity.

A problem seems to exist in this article with respect to interpretation of some of the data. On page 3 the authors note that 58% of the sample falls in cells not on the main diagonal of Table 1 and this suggests the presence of temporal incongruity. "Nearly 28% (above the main diagonal) appear to be spending less time than preferred, while 30% (below the main diagonal) appears to be spending more time than preferred." It would seem that what is really the case is that only those respondents who found enjoyment of meal preparation to be "neutral" are temporally congruent, while those who found meal preparation to be less or more enjoyable regardless of the minutes/week spent in the activity are temporally incongruent. On page 4 the authors state "respondents who are spending less time cooking than desired may continue to

demand time-intensive foods and modes of preparation and ignore time saving goods and services." Fully employed, single women fall into this category per the data analysis; however, do fully employed single women demand time-intensive food or are they a prime market for microwave ovens? Why this incongruity exists is not clear. Perhaps because there is a weak relationship between time spent on cooking and enjoyment. Enjoyment does not appear to be a good surrogate for time one would like to spend on cooking. Because of this weak relationship the results could be the same for analysis using standard AID techniques, rather than AID covariates. Another possibility would be the use of standard regression analysis using dummy variables for the 8 segments identified. While the AID covariate analysis searches for intercept dummy variables, it might be interesting to look for slope dummy variables. I agree with the authors' concluding comment "... this discussion of the concept of temporal incongruity will stimulate research ..." The authors are to be commended for the early development and examination of this concept.

The final article reviewed here by Holman, "The Imagination of the Future: A Hidden Concept in the Study of Consumer Decision Making" provides a valuable review of a concept that could perhaps play a role in gaining greater understanding of consumer behavior. As the author points out, research on time has focused mainly on the allocation process. A consumer's imagination of and orientation toward the future could have significant impact on buying behavior. While the author provides no empirical results toward this end, she does raise a number of interesting questions at the end of the article. Another problem, as the author indicates, is the lack of an instrument to operationalize the concept of future imagery. Perhaps if the author's literature review had been broadened to include industrial buying behavior and marketing management this problem would have been somewhat diminished. Long range forecasting and strategic planning techniques are methodologies used by organizations to operationalize the future imagery of the market place for their goods and services. Perhaps these or similar processes operate within individuals when they consider and plan for the future. Obviously, the process within individuals is not as overt or attempted to be rational but parallels may exist. The fact that differences exist within individuals concerning belief in conceptualization of the future presents interesting problems for consumer behavior researchers with respect to measurement of and prediction from behavioral intentions. Behavioral intentions must interact with future imagery. The author could have gone further in drawing out the possible ramifications of this interaction and what might be done to control for it. The author is to be commended for her effort in bringing together literature of a highly interdisciplinary nature and demonstrating its potential to impact upon the understanding of consumer behavior. I hope that the author will follow this probe into the imagination of the future by developing an instrument to operationalize the concept of future imagery and providing some empirical results.

Conclusion

The consumer behavior and marketing literature has included both implicit and explicit treatment of the time dimension in concepts, models, and managerial decision making studies. However, this treatment has been sporadic and has lacked coordination. Studying the effects of time on consumer behavior from a cross-sectional perspective such as perception of the future and feelings of temporal incongruity provide some increases in knowledge of consumer behavior but seem to avoid the main effect of time on consumer behavior. More longitudinal studies are required for understanding and better measurement of changes in consumer behavior over time.

CAUSAL MODELING: A GENERAL METHOD FOR DEVELOPING
AND TESTING THEORIES IN CONSUMER RESEARCH

Richard P. Bagozzi, Massachusetts Institute of Technology

Introduction

The behavioral sciences are now experiencing a revolution of sorts that is dramatically influencing the way researchers are approaching problems. The revolution entails a paradigm shift away from the many fragmented methods for inquiry currently employed toward a more holistic framework termed herein causal modeling. The purpose of this article is to outline and illustrate the use of causal modeling in consumer research. To this end, the expectancy-value model of attitude will be examined.

Before presentation of the approach, however, it will prove useful to provide some background. Causal modeling is often regarded by the unfamiliar as merely another data analytic technique to be used primarily in survey research. In reality, it is a method of enormous scope and power, where 'method' is taken here in its broadest philosophy of science sense.

In particular, we may look at causal modeling from at least four perspectives. First, causal modeling is a general philosophical orientation. It provides a way to operationalize the commonly accepted model of scientific inquiry posed by philosophers of science which stipulates that any true theory must contain, at a minimum, theoretical concepts, empirical observations, correspondence rules that link theoretical concepts to observations, and a rationale or set of laws connecting theoretical concepts (Bagozzi 1979). Further, when used as a tool for causal inference, causal modeling proceeds from a set of philosophical principles which guide the specification, test, and interpretation of any theory. Typically, the researcher will use either a neo-positivist or realist conceptualization of causation when employing causal modeling (Bagozzi 1980a).

Despite its common sense meaning, causal modeling is not limited to studies of cause-and-effect. Indeed, from a second perspective, causal modeling can be employed strictly in a measurement sense to compute internal consistency and test-retest reliabilities. Significantly, it allows the researcher the opportunity to assess a whole family of traditional measures of reliability such as Cronbach Alpha, as well as more general alternatives. It does this with less information than is required by traditional procedures in some instances, and it provides a means to take into account errors in variables and systematic error such as methods variance or other external confounds.

Third, causal modeling can be a valuable methodology for the examination of construct validity. Not only can it be used to perform a traditional multitrait-multimethod matrix analysis, but it does this in a more rigorous and less ambiguous way. Moreover, causal modeling furnishes one with a versatile means to investigate other forms of validity such as criterion related, predictive, and nomological validities. An important point to note is that causal modeling offers the advantage over traditional methods that measurement error is taken into account explicitly.

Finally, causal modeling is a general method for testing hypotheses. It can be used expediently in true experiments, quasi-experiments, cross-sectional surveys, panel studies, time series analyses, and cohort investigations, to name

a few contexts. As in measurement and construct validation usages, it offers the opportunity to take into account measurement error as well as systematic biases. For example, the causal modeling analogue to the analysis of covariance in experimental settings gives a straight forward way to accurately correct for random error, adjust for differences between experimental and control groups, and generally model the influence of non-random factors. In this sense, it avoids the major limitation of the traditional analysis of covariance which, by failing to take into account errors in variables, can sometimes fail to detect a true causal effect or else erroneously identify an effect which does not in fact exist.

As important as causal modeling portends to be, it is not without faults and shortcomings. A statement of these and some of its benefits are presented at the end of this article. For further explication of causal modeling, the reader is referred to Bagozzi (1980a), Bentler (1980), and Jöreskog and Sörbom (1979). We turn now to a prototypic development of causal modeling as a method of research.

Causal Modeling in Theory
Development and Hypothesis Testing

To illustrate causal modeling, consider the expectancy-value model of attitude and image that one desires to examine its nature, measurement, antecedents, and implications. One way to do this is to scrutinize the following issues: (1) convergent validity, (2) reliability, (3) concurrent validity, (4) discriminant validity, (5) predictive validity, and (6) nomological validity.¹ A verbal definition and mathematical expression for each of these follows.

Convergent Validity

At an intuitive level, convergent validity can be conceived as the extent to which two or more attempts to measure the same concept through maximally different methods are in agreement. The traditional standard for convergence requires that the correlations between measures of the same concept be greater than zero, statistically significant, and relatively large. However, because these criteria do not specifically take into account measurement error and can be misleading, the more rigorous causal modeling method will be used herein.

The null hypothesis for the causal model of convergence for an unidimensional attitudinal construct can be expressed as

¹Two additional standards that should be examined are the theoretical meaningfulness and the observational meaningfulness of concepts in the theory. The former refers to certain logic criteria as to well-formedness, internal consistency, and the like; while the latter concerns the adequacy of correspondence rules relating theoretical concepts to observed measures. In the interest of brevity, these criteria will not be analyzed here, and the reader is referred to other treatments of these issues by the author (Bagozzi 1979, 1980a, 1980b).

$$\underline{y} = \underline{\Lambda} \underline{x} + \underline{z} \quad (1)$$

where \underline{y} is a vector of p observations of attitude (y_1, y_2, \dots, y_p); \underline{x} is a hypothesized attitudinal construct; $\underline{\Lambda}$ is a vector of factor loadings relating \underline{y} to \underline{x} ; and \underline{z} is a vector of unique scores (i.e., errors in variables). The attitudinal construct, \underline{x} , is taken as an expectancy-value model where each y_i consists of the product of an expectancy (belief)-times-value observation. To fully specify the null hypothesis for the unidimensional attitudinal construct, the variance-covariance matrix of observations, $\underline{\Sigma}$, must be written as

$$\underline{\Sigma} = \underline{\Lambda} \underline{\Lambda}' + \underline{\Psi} \quad (2)$$

where $\underline{\Psi}$ is a diagonal matrix of error variances for attitudinal measures. In words, equations (1) and (2) hypothesize that all of the variation in responses to the attitudinal measures can be accounted for by one underlying expectancy-value construct, except for random error.

The null hypothesis for the causal model of convergence for a multidimensional attitudinal construct can be expressed as

$$\underline{y} = \underline{\Lambda} \underline{x} + \underline{z} \quad (3)$$

$$\underline{\Sigma} = \underline{\Lambda} \underline{\Phi} \underline{\Lambda}' + \underline{\Psi} \quad (4)$$

where \underline{x} is now a $k < p$ vector of hypothesized attitudinal dimensions, $\underline{\Phi}$ is the intercorrelation matrix of attitudinal dimensions, and the remaining symbols are as defined earlier. As a point of interpretation, equations (3) and (4) hypothesize that all of the variation in attitudinal responses can be accounted for by k oblique dimensions, except for random error. This will occur when the responses of subjects (a) achieve a high degree of convergence among measures within attitudinal dimensions (i.e., when the within dimension measures are both highly intercorrelated and uniform in their pattern of values) and (b) exhibit uniform and significantly lower correlations among measures across dimensions. Figure 1 shows a causal diagram which is, in fact, the model achieving construct validity in the present study.

FIGURE 1

Causal Diagram for Convergent Validity

Reliability

Two internal consistency measures of reliability can be effectively applied to observations. The reliability of individual items, p_i , can be computed as

$$p_i = \frac{\lambda_i^2 \text{var } x_j}{\lambda_i^2 \text{var } x_j + \psi_i} \quad (5)$$

where λ_i is the factor loading relating the i th measure of attitude (i.e., the i th belief times evaluation product) to its respective attitudinal dimension, x_j ; and the remaining symbols are as defined earlier. Similarly, the reliability of a composite, p_c , of r observations of x_j can be calculated as

$$p_c = \frac{\left(\sum_{i=1}^r \lambda_i \right)^2 \text{var } x_j}{\left(\sum_{i=1}^r \lambda_i \right)^2 \text{var } x_j + \sum_{i=1}^r \psi_i} \quad (6)$$

As with Cronbach Alpha, p_i and p_c should only be applied to unidimensional attitude scales (or to homogeneous subdimensions) because to do otherwise would capitalize on the shared variance across dimensions and yield generally inflated values. Hence, it is recommended that one examine convergent validity first before computing reliabilities. Finally, it should be noted that equation (6) is similar to the standard Cronbach Alpha formula except that the latter assumes, a priori, that each observation of x_j contributes equally (i.e., the λ_i 's are set equal to unity). Thus, equation (6) is more general and less restrictive than Cronbach Alpha.

Concurrent Validity

The degree to which a measure of a concept correlates with a measure of a similar concept when both should naturally covary is known as concurrent validity (which itself is a special case of criterion-related validity). In the present research, concurrent validity will be examined as the degree of association between the attitude toward the act (measured with five semantic differential items) and the expectancy-value model of attitude. Figure 2 illustrates a causal diagram for concurrent validity when attitude toward the act (Aact) exists as an unidimensional construct and the expectancy-value model is multidimensional.

The null hypothesis for the concurrent validity model of Figure 2 is

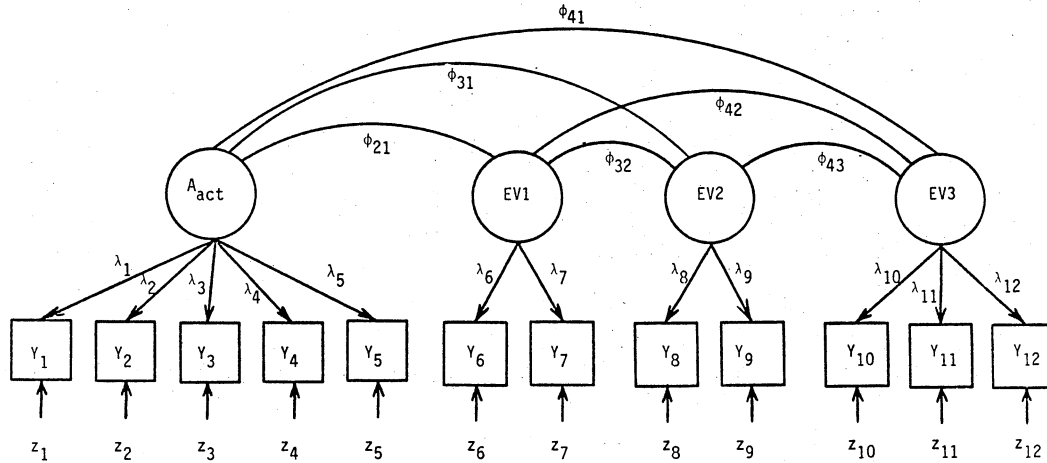

$$\underline{y} = \underline{\Lambda} \underline{x} + \underline{z} \quad (7)$$

$$\underline{\Sigma} = \underline{\Lambda} \underline{\Phi} \underline{\Lambda}' + \underline{\Psi} \quad (8)$$

where $\underline{y} = (y_1, y_2, \dots, y_{12})'$, $\underline{x} = (\text{Aact}, \text{EV1}, \text{EV2}, \text{EV2})'$, $\underline{z} = (z_1, z_2, \dots, z_{12})'$,

FIGURE 2

Causal Diagram For Concurrent and Discriminant Validity

$$\Lambda = \begin{bmatrix} \lambda_1 & 0 & 0 & 0 \\ \lambda_2 & 0 & 0 & 0 \\ \lambda_3 & 0 & 0 & 0 \\ \lambda_4 & 0 & 0 & 0 \\ \lambda_5 & 0 & 0 & 0 \\ 0 & \lambda_6 & 0 & 0 \\ 0 & \lambda_7 & 0 & 0 \\ 0 & 0 & \lambda_8 & 0 \\ 0 & 0 & \lambda_9 & 0 \\ 0 & 0 & 0 & \lambda_{10} \\ 0 & 0 & 0 & \lambda_{11} \\ 0 & 0 & 0 & \lambda_{12} \end{bmatrix}, \text{ and } \Phi = \begin{bmatrix} 1.000 & & & \\ \phi_{21} & 1.000 & & \\ \phi_{31} & \phi_{32} & 1.000 & \\ \phi_{41} & \phi_{42} & \phi_{43} & 1.000 \end{bmatrix}$$

This is a stringent test of concurrent validity because the hypothesis will be sustained only when (a) the within dimension correlations of measures are high, statistically significant, and uniform and (b) the across dimension correlations of measures are uniform and significantly lower than the within dimension values. Given this state of affairs, concurrent validity can be assessed by examination of ϕ_{21} , ϕ_{31} , and ϕ_{41} (i.e., the correlations between the attitude toward the act and the expectancy-value dimensions). These cross dimension correlations should be relatively high and statistically significant, yet should be lower in magnitude than ϕ_{32} , ϕ_{42} , and ϕ_{43} which, in turn, represent the intercorrelations among the three expectancy-value dimensions.

Discriminant Validity

Discriminant Validity refers to the degree to which a concept differs from other concepts. Given the establishment of convergent validity, discriminant validity can be examined through an inspection of ϕ_{21} , ϕ_{31} , and ϕ_{41} (see Figure 2). The comparison of the goodness-of-fit tests for the model of Figure 2 where ϕ_{21} , ϕ_{31} , and ϕ_{41} are left unconstrained to the same model wherein ϕ_{21} , ϕ_{31} , and

ϕ_{41} are constrained to equal unity will provide an explicit test of discriminant validity. The successful achievement of convergence and discrimination as outlined heretofore would indicate that one's construct (attitude) is valid in the sense of achieving homogeneity and uniqueness.

Predictive Validity

If a measure of a concept is related empirically as an antecedent to, or consequent of, a measure of another concept, then it is said to achieve predictive validity. The relation should not be fortuitous but rather should have its basis in the mechanism or theory connecting the two concepts.

The predictive validity of the expectancy-value model will be examined in two senses. As a predicted variable, the expectancy-value model will be observed as a function of the extent of the performance of past behavior, where the behavior relates directly to the act encompassed by the content of attitude. As a predictor, the expectancy-value model will be investigated as it forecasts three behavioral intentions that are logically entailed by a favorable attitude.

Specifically, Figure 3 and 4 show the expectancy-value model as a predicted and predictor variable, respectively. In Figure 3, past behavior (PB) is proposed to be antecedent to three expectancy-value dimensions. The structural equations for the null hypothesis of this model are

$$\begin{bmatrix} EV1 \\ EV2 \\ EV3 \end{bmatrix} = \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} [PB] + \begin{bmatrix} \zeta_1 \\ \zeta_2 \\ \zeta_3 \end{bmatrix}$$

Figure 4 posits that the expectancy-value model (EV) predicts three behavioral intentions (BI1, BI2, BI3). The structural equations for the null hypothesis of this model are

$$\begin{bmatrix} BI1 \\ BI2 \\ BI3 \end{bmatrix} = \begin{bmatrix} \gamma_1 \\ \gamma_2 \\ \gamma_3 \end{bmatrix} [EV] + \begin{bmatrix} \zeta_1 \\ \zeta_2 \\ \zeta_3 \end{bmatrix} \tag{10}$$

FIGURE 3

Causal Diagram For Predictive Validity:
Past Behavior Predicting Attitude
(correlations among ζ 's omitted for simplicity)

FIGURE 4

Causal Diagram For Predictive Validity:
Attitude Predicting Behavioral Intentions
(correlations among ζ 's omitted for simplicity)

A single construct is used to represent the expectancy-value model in order to avoid problems of multicollinearity which would exist had one employed the three dimensions -- EV1, EV2, EV3 -- as simultaneous predictors. The three measures of EV are, respectively:

$$x_1 = \sum_{i=1}^2 e_i v_i, \quad x_2 = \sum_{i=3}^4 e_i v_i, \quad \text{and} \quad x_3 = \sum_{i=5}^7 e_i v_i$$

where e_i and v_i are respectively, particular belief and evaluation items from a questionnaire.

Nomological Validity

Nomological validity indicates the degree to which predictions from a formal theoretical network containing a concept of interest are confirmed. From one viewpoint, the difference between predictive and nomological validities might be regarded as one of degree and not kind. Predictive validity entails the relationship of a concept to a single antecedent or consequent. Nomological validity in contrast, involves many antecedents and/or consequents in a complex theoretical system. The particular test of the nomological validity of the expectancy-value model conducted herein is based on attitude and learning theory (see Bagozzi 1980b). That is, it is hypothesized that a person's intentions to act in a particular way will be a function of (a) one's beliefs about the consequence of performing the behavior and the evaluation of those consequences (i.e., the expectancy-value attitude), (b) the extent of having performed the behavior in the past, (c) one's personal normative belief (PNB) that he or she should perform the behavior, and (d) one's social normative belief (SNB) that others whose opinions are valued feel that he or she should perform the behavior.

Figure 5 illustrates the null hypothesis for the nomological validity model. The structural equations for the key relations are

$$\begin{bmatrix} BI1 \\ BI2 \\ BI3 \end{bmatrix} = \begin{bmatrix} \gamma_1 & \gamma_4 & \gamma_7 & \gamma_{10} \\ \gamma_2 & \gamma_5 & \gamma_8 & \gamma_{11} \\ \gamma_3 & \gamma_6 & \gamma_9 & \gamma_{12} \end{bmatrix} \begin{bmatrix} EV \\ PB \\ PNB \\ SNB \end{bmatrix} + \begin{bmatrix} \zeta_1 \\ \zeta_2 \\ \zeta_3 \end{bmatrix} \quad (11)$$

Background of Study

The foregoing hypotheses were examined in the context of attitudes toward the act of donating blood. The results presented here constitute analyses performed on a sub-sample of 127 faculty, students, and staff which was drawn from part of a larger study. The full study was a quasi-experiment performed by the author (Bagozzi 1980b) and, for purposes of description, can be termed a post-test only design with nonequivalent multiple groups, multiple covariates, and measurement error modeled explicitly. Although a total of eight complex hypotheses were tested across and within groups on main effects and slope effects, only part of the within group analyses for one of three groups will be investigated herein. This is necessary for purposes of brevity, given space constraints. Hence, the present study is a survey analysis. The reader is urged to examine the quasi-experiment presented in Bagozzi (1980b), in order to gain a more complete picture of the scope and power of causal modeling. Also, the author presents a detailed description of the pre-tests, questionnaire, sample, methodology, and other related issues. Jöreskog and Sörbom's (1978) program, LISREL, was used for all analyses.

FIGURE 5

Causal Diagram For Nomological Validity
(correlations among ζ 's and among exogenous variables omitted for simplicity)

Results

On the hypothesis that people would form complex multi-dimensional expectancy-value attitudes rather than unidimensional ones (see Bagozzi 1980b for the rationale), convergent validity was examined. As predicted, the responses to the seven expectancy times value products did not converge to yield a single underlying attitudinal construct ($\chi(14) = 72.95, p \approx .00$). However, convergence was achieved for the multidimensional expectancy-value model, as hypothesized ($\chi^2(11) = 5.86, p \approx .88$). The second and third columns of Table 1 list the factor loadings and error variances, respectively, for the 7 expectancy times value products described in column one. Notice that each loading is relatively large in value and twice its respective standard error, and the error variances are low to moderate in magnitude.

Column four in Table 1 shows the individual item reliabilities where it can be seen that all values reach acceptable levels except the seventh which should be regarded as borderline. As presented in the final column of Table 1, the composite reliabilities are quite large in magnitude and thus indicate that the measures of the three dimensions of the expectancy-value model exhibit a high degree of internal consistency.

The goodness-of-fit test for the model testing concurrent validity shows that the hypothesis cannot be rejected (i.e., $\chi^2(48) = 56.96, p \approx .18$). The intercorrelation matrix of Aact, EV1, EV2, and EV3 is

	Aact	EV1	EV2	EV3
$\phi =$	1.000			
	.413	1.000		
	.527	.670	1.000	
	.497	.786	.785	1.000

Each of the correlations between Aact and the EVi is statistically significant at the .001 level or better and is lower than the correlations among the EVi.

Because the likelihood functions for the model represented by equations (7) and (8) could not be evaluated when ϕ_{21} , ϕ_{31} , and ϕ_{41} were constrained to unity, it was not possible to examine the difference in χ^2 -tests necessary for an explicit test of discriminant validity. However, inspection of ϕ indicates that the relevant entries are each far below 1.000, with the differences being greater than the values necessary to achieve significance at the .001 level or better. Thus, the evidence suggests that the expectancy-value model achieves uniqueness when compared to the semantic differential operationalization of attitude toward the act.²

² It should be noted that Aact, itself, attained convergent validity ($\chi^2(5) = 4.16, p \approx .53$) and demonstrated high individual ($p_i = .500$ to $.788$) and composite ($p_c = .916$) reliabilities. The expectancy-value model is largely a cognitive measure of attitude, while Aact is predominantly affective in content.

Table 2 summarizes the results for predictive validity. Looking first at column one, we can see that past behavior predicts all three behavioral intentions³, as hypothesized. All parameter values are in the proper direction and are at least twice their standard errors; and the overall goodness-of-fit test indicates a very good correspondence indeed ($\chi^2(16) = 7.67, p = .96$). The findings for the expectancy-value model as a predictor are shown in column two of Table 2. In general, the results are mixed. Although the goodness-of-fit test indicates a poor fit overall ($\chi^2(6) = 22.93, p = .00$), the parameter values are in the proper direction and are greater than twice their respective errors. Moreover, inspection of the residual matrix shows that the model captures most of the variation in responses.

Table 3 presents the results for the test of nomological validity. The overall goodness-of-fit test indicates a borderline fit ($\chi^2(18) = 28.22, p = .06$). Notice that the expectancy-value model predicts all three behavioral intentions significantly and in the predicted direction and that two of the three intentions are predicted by past behavior. Neither personal normative beliefs nor social normative beliefs function as significant predictors of behavioral intentions, however. Apparently, future volitions are only under the control of attitudes and past behavior.

But are they in reality? The results of the quasi-experiment suggest that attitudes are not validly related to intentions at all (Bagozzi 1980b). The findings in Table 3 are based on a sample of individuals who had given blood 20 minutes prior to filling-out the questionnaire or less. These individuals thus could have inferred their attitudes from their own prior behavior; and attribution and self-perception arguments could serve as rival explanations for the observed relations. However, when this sample was compared to a second sample of previous donors who had last given blood two months prior to filling-out the questionnaire or longer, only past behavior functioned as a valid determinant of intentions. It appears that attitudes do not supply any predictive power over and above learning theory arguments. Similarly, attitudes failed to predict intentions for those who had never given blood in the past. In sum, while considerable evidence exists for (a) the convergent, concurrent, discriminant, and predictive validities of the expectancy-value model of attitude, (b) reliability in measurement of attitudes, and (c) a valid relation from behavior to attitude, one must question the hypothesis that attitudes influence intentions.

As a point of comparison, it should be noted that it would not have been legitimate to use the commonly computed Fishbein model which is formed by summing the expectancy times value products to arrive at a single number for the expectancy-value attitude. The Fishbein model is justifiable only when the items form a unidimensional scale. Although few authors have ever demonstrated the reliability and validity of their measures (see Bagozzi 1980b for a review), the practice has been in consumer research to merely rely on the face validity of the expectancy-value

³Two of the behavioral intention items asked the probability one would (a) give blood "sometimes in the future" and (b) become a regular donor, respectively. These were measured on 11-point scales. The third behavioral intention item asked how frequently one might give blood if they had become a regular donor and was measured on a 7-point scale ranging from "5 times per year" to "would not become a regular donor."

model and to assume unidimensionality. For discussions and illustrations of the problems entailed by this practice, see Bagozzi (1980b,c).

Unresolved Issues

A number of shortcomings of the causal modeling method deserve mention. First, because the goodness-of-fit chi-square test is directly proportional to sample size, it is likely that virtually all models will be rejected in very large samples. There are at least three ways to mitigate this limitation. One alternative is to confine one's analysis to comparisons among nested models and to examine the differences in chi-square tests. This provides a means to assess the tenability of valid causal paths. A second procedure that might be meaningful in certain contexts is to randomly select subsamples from a larger population and then perform the causal analysis on these subsamples. One could then test the invariance of key parameters across subsamples, as well as examine the goodness-of-fit tests for each subsample. This approach might be useful when one desires to use separate fitting and validation samples. A third alternative is to scrutinize the residual matrix and ascertain whether the amount of information remaining is trivial for all practical purposes. Combinations of all three procedures might prove effective in some cases.

A second limitation of causal modeling is that it is strictly appropriate to use only large samples. Although what constitutes a large sample is open to question, this author has found that in many instances it is justifiable to employ causal modeling when the sample size minus the number of parameters to be estimated is greater than about 50. Hence, for most applications, the sample should be at least 60 to 70, or so. Unfortunately, very little is known about the small sample properties of the parameter estimates generated by LISREL, although some work is now being performed in this regard by statisticians. Hence, use of the procedures with small samples must be regarded with caution.

A third shortcoming of causal modeling is that it is designed to be used with measures that are at least interval scaled. Very little is known about the consequences of using measures that are ordinal. However, if one forms measures as the sum of independently distributed ordinal measures, say, then it is probably safe to assume that the summed variates satisfy the normality assumptions. Further, if the distribution of responses to variables is not too excessively skewed and if many scale steps are used (say seven or more), then the distributional assumptions of causal modeling may not be violated detrimentally for many applications. When in doubt, it is best to check the distributional properties of one's observations. Jöreskog and Sörbom (1978, p. 13) provide references for procedures to "robustify" one's data.

Still another limitation is the requirement that hypothesized relations be linear. This will not pose problems generally when transformations can be made to the data to reflect nonlinearities or when the underlying processes being modeled are linear to approach being linear. However, when such is not the case, causal modeling becomes less useful.

A final problem to note concerns the framework for hypotheses. Causal modeling sets-up the null hypothesis such that a nonsignificant chi-square value indicates a satisfactory fit. Ordinarily, one prefers that the hypothesis be constructed in an opposite way, but this is impossible to do so. In practice, the causal modeling approach usually gives valid results. Moreover, Bentler (1980) suggests the use of an index of the amount of information gained as a partial solution to the null hypothesis dilemma.

Conclusion

It is important to stress that causal modeling represents only one link in the research process. Issues such as concept formation, questionnaire development, sampling, overall research design (e.g., random assignment and construction of experimental procedures), and the interpretation of findings are equally important areas for concern. Causal modeling should not be regarded as a replacement for any of these; indeed, each constitutes a necessary step in the process. Rather, causal modeling supplies the researcher with a powerful method for improving the conduct of research, given that care has been taken at all points in the process.

A COMPARISON OF CAUSAL PATH AND ECONOMETRIC MODELING APPROACHES

Leonard J. Parsons, Georgia Institute of Technology

Abstract

A tutorial is given on causal path and econometric modeling in consumer behavior. The conclusion is that conventional path-analytic techniques add little to the more substantial body of econometric theory and practice.

Introduction

Path analysis has been the primary methodology used in a spate of recent marketing papers (Lutz 1977, Moschis and Moore 1978, Bearden, Gustafson, and Mason 1978, Teas, Wacker, and Hughes 1979, Bearden, Teal, and Crocket 1980). These papers may have been influenced by an earlier piece by Christopher and Elliott (1970).

On the other hand, econometrics has had a long tradition in the study of buyer behavior. Applications range from an evaluation of the hypothesis of a hierarchy of effects (Palda 1966) to a test of Howard and Sheth's model of behavior (Farley and Ring 1970, 1972).

The purpose of this paper is to provide a brief tutorial on econometric and path analytic modeling. The goal is to assess what, if anything, path analysis adds to conventional econometric methodology. The paper begins with a review of selected aspects of econometrics, follows with an econometric reanalysis of a marketing path-analytic investigation, reviews the technique of path analysis, redoes the previous example from the perspective of path analysis, and ends with a comparison of the approaches. The discussion will be restricted to linear models and will omit the detail underlying the methodologies.

Econometric Modeling

Parsons and Schultz (1976) argued that the scope of econometric research as applied to marketing must be broadened to include theory development as well as measurement and testing processes. They were interested in causal modeling and set forth eight "standards" necessary for econometric studies to qualify as causal models. They suggested that many applications of regression analysis in marketing failed to meet their criteria.

The construction of causal models begins by developing a theory of marketing behavior and expressing this theory as a set of mathematical relations, a model. The existence of a theory which predicts a relationship among the variables within an equation causes the equation to be called structural. This theory provides the a priori information necessary to perceive the structure to be estimated, that is, to distinguish it from the other structures capable of generating the observed data. This is known as the identification problem.

A linear model can be expressed in matrix notation as

$$Y\Gamma + XB = E. \tag{1}$$

Only models containing as many equations as current endogenous variables will be considered. When this condition is met, the system is said to be complete. Suppose there are n observations on a system of L equations. Then the data on the current endogenous variables are placed in the matrix Y. The observations on the predetermined variables, either exogenous or lagged endogenous or both, are found in the matrix X.

Since the system is complete, the matrix Γ is assumed to be nonsingular. The coefficients of the predetermined variables in each equation are contained in the matrix B.

$$\Gamma = \begin{bmatrix} -1 & \gamma_{12} & \dots & \gamma_{1L} \\ \gamma_{21} & -1 & \dots & \gamma_{2L} \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_{L1} & \gamma_{L2} & \dots & -1 \end{bmatrix} \quad B = \begin{bmatrix} \beta_{11} & \beta_{12} & \dots & \beta_{1L} \\ \beta_{21} & \beta_{22} & \dots & \beta_{2L} \\ \vdots & \vdots & \ddots & \vdots \\ \beta_{k1} & \beta_{k2} & \dots & \beta_{kL} \end{bmatrix} \tag{2}$$

The equations have been arranged so that the ith variable in the ith equation is that equation's dependent variable.

Finally, the disturbances are contained in the matrix E. The rows of the disturbance matrix are assumed to be stochastically independent and identically distributed with zero mean vector and an unknown but finite covariance matrix Σ .

$$\Sigma = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \dots & \sigma_{1L} \\ \sigma_{21} & \sigma_{22} & \dots & \sigma_{2L} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{L1} & \sigma_{L2} & \dots & \sigma_{LL} \end{bmatrix} \tag{3}$$

The matrix Σ , the contemporaneous covariance matrix of disturbances in different equations, is the same for all periods.

Our discussion will be facilitated by a classification scheme based upon the nature of the matrix of coefficients of the current endogenous variables Γ and the contemporaneous covariance matrix Σ . The first step is to examine the matrix Γ . If the matrix Γ is diagonal, the matrix Σ is examined. If the matrix Σ is diagonal, there are no relationships among the equations and each can be treated as a separate single equation model. If it is not diagonal, there is a seemingly unrelated equations system. If the matrix Γ is triangular and the matrix Σ diagonal, there is a recursive equations system. For the remaining categories involving the matrix Γ and the matrix Σ , there is an interdependent simultaneous equations system. Figure 1 presents a diagram of this classification process.

FIGURE 1

CLASSIFICATION OF SIMULTANEOUS EQUATION SYSTEMS

The structural equation system can be transformed into a logically equivalent system of equations in which each member equation contains only one endogenous variable:

$$Y = -XB\Gamma^{-1} + E\Gamma^{-1} \equiv X\Pi + U. \quad (4)$$

This new system is called the reduced form. Each reduced-form equation contains all the predetermined variables in an equation system. The contemporaneous covariance matrix of the reduced-form disturbances is

$$\Omega = (\Gamma')^{-1} \Sigma \Gamma^{-1} \quad (5)$$

The ability to express the structural parameters as explicit functions of the reduced-form parameters is unfortunately not automatic and, indeed is sometimes impossible. Determination of whether there is a one-to-one correspondence between the structural parameters and the reduced-form parameters is called the identification problem. Identification is logically prior to estimation. A discussion of how to test whether the relationships in system are identifiable as well as of how to apply such tests to Farley and Ring's operational version of the Howard-Sheth model of buyer behavior is given in Parsons and Schultz (1976).

If the identifiability condition is met, the parameters of the model can then be estimated. The alternative techniques include ordinary least squares, generalized least squares, seemingly unrelated equations estimation, indirect least squares, two-stage least squares, and three-stage least squares. Parsons and Schultz (1976, pp. 65-78) suggest which technique to use depending upon the structure of a model.

An Example

The heart of recent investigation of life satisfaction among elderly consumers (Bearden, Gustafson, and Mason 1978) is a two equation model. The variables can be defined in deviation form and consequently there are no intercepts shown in the equations. The first relationship says that satisfaction with level of living, X_4 , is a function of the level of alienation, X_3 , and a disturbance term, ϵ_4 or

$$X_4 = b_{43} X_3 + \epsilon_4. \quad (6)$$

The second relationship postulates that overall life satisfaction, X_6 , is a function of living level satisfaction, now an intervening variable, alienation, and health situation, X_1 , and another disturbance terms, ϵ_6 , or

$$X_6 = b_{61} X_1 + b_{63} X_3 + b_{64} X_4 + \epsilon_6. \quad (7)$$

The disturbances are assumed to be independent of one another, i.e., $\sigma_{46} = 0$. Moreover, alienation and health situation are explicitly believed to be intercorrelated. Alienation affects overall life satisfaction indirectly through living level satisfaction as well as directly. The data for this example are given in Table 1.

TABLE 1

VARIABLE CORRELATIONS, MEANS, AND STANDARD DEVIATIONS^a

Variable	X1	X3	X4	\bar{X}	s
X1: Health Situation	1.000			12.35	2.50
X3: Alienation	.374	1.000		72.08	12.16
X4: Living Level Satisfaction	.150	.259	1.000	2.59	.63
X6: Life Satisfaction	.361	.452	.346	16.06	3.37

^aSource: Bearden, Gustafson, and Mason (1977, p.387)

Using the matrix notation introduced earlier, the key matrices for this two equation system are

$$\Gamma = \begin{bmatrix} -1 & b_{64} \\ 0 & -1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & b_{61} \\ b_{43} & b_{63} \end{bmatrix}, \quad \text{and} \quad \Sigma = \begin{bmatrix} \sigma_{44} & 0 \\ 0 & \sigma_{66} \end{bmatrix}.$$

Given our classification scheme, this simultaneous equation system is said to be recursive.

The parameters of the corresponding reduced-form equations are

$$\Pi = -B\Gamma^{-1} \quad (8)$$

or

$$\begin{bmatrix} \Pi_{41} & \Pi_{61} \\ \Pi_{43} & \Pi_{63} \end{bmatrix} = \begin{bmatrix} 0 & b_{61} \\ b_{43} & b_{63} \end{bmatrix} \begin{bmatrix} 1 & -b_{64} \\ 0 & 1 \end{bmatrix}^{-1} \\ = \begin{bmatrix} 0 & b_{61} \\ b_{43} & b_{63} \end{bmatrix} \begin{bmatrix} 1 & b_{64} \\ 0 & 1 \end{bmatrix} \\ = \begin{bmatrix} 0 & b_{61} \\ b_{43} & b_{64}b_{43} + b_{63} \end{bmatrix} \quad (9)$$

Because the model is recursive each equation can be estimated by ordinary least square regression. The least squares estimator for a given equation is

$$\hat{\beta} = (X'X)^{-1} X'y. \quad (10)$$

If we write

$$S_{XX} = (X'X)/n \quad \text{and} \quad s_{xy} = (X'y)/n$$

we can express the estimator in terms of covariances

$$\hat{\beta} = (S_{XX})^{-1} s_{xy}. \quad (11)$$

For the first equation the estimated parameter is simply

$$b_{43} = (s_3^2)^{-1}(s_{34}) = (147.866)^{-1} (1.984) = .0134.$$

The estimated parameters in the second equation are

$$\begin{bmatrix} b_{61} \\ b_{63} \\ b_{64} \end{bmatrix} = \begin{bmatrix} s_1^2 & s_{13} & s_{14} \\ s_{13} & s_3^2 & s_{34} \\ s_{14} & s_{34} & s_4^2 \end{bmatrix}^{-1} \begin{bmatrix} s_{16} \\ s_{36} \\ s_{46} \end{bmatrix} \\ = \begin{bmatrix} 3.250 & 4.252 & .236 \\ 4.252 & 147.866 & 1.984 \\ .236 & 1.984 & .397 \end{bmatrix}^{-1} \begin{bmatrix} 3.041 \\ 18.523 \\ .735 \end{bmatrix} = \begin{bmatrix} 1.249 \\ .069 \\ .281 \end{bmatrix}$$

Sometimes there is interest in the "relative contribution" of each term in the regression and the beta coefficients are calculated. The beta coefficient is

$$\text{beta}_{ij} = (s_j/s_i)b_{ij}$$

where x_i is the dependent variable and x_j is a predetermined variable. This is equivalent to running ordinary least squares regression on standardized variables. The result is that the estimator is expressed in terms of the sample correlation matrix

$$\underline{\beta} = R_{xx}^{-1} r_{xy}. \text{ Thus, } \beta_{43} = (1)^{-1} r_{34} = .259 \quad (12)$$

and for the second equation

$$\begin{bmatrix} \beta_{61} \\ \beta_{63} \\ \beta_{64} \end{bmatrix} = \begin{bmatrix} 1.0 & r_{13} & r_{14} \\ r_{13} & 1.0 & r_{34} \\ r_{14} & r_{34} & r_{46} \end{bmatrix}^{-1} \begin{bmatrix} r_{16} \\ r_{36} \\ r_{46} \end{bmatrix} \quad (13)$$

$$\begin{bmatrix} \beta_{61} \\ \beta_{63} \\ \beta_{64} \end{bmatrix} = \begin{bmatrix} 1.000 & .374 & .150 \\ .374 & 1.000 & .259 \\ .150 & .259 & 1.000 \end{bmatrix}^{-1} \begin{bmatrix} .361 \\ .452 \\ .346 \end{bmatrix}$$

$$= \begin{bmatrix} .209 \\ .313 \\ .234 \end{bmatrix}$$

A summary of these results as well as those for the reduced-form equations are given in Table 2.

Causal Path Analysis

Causal path analysis was developed by a geneticist (Wright 1921, 1934) as a means of relating correlation coefficients between variables in a system to the functional relations among them. Path analysis has been used in psychology (Werts and Linn, 1970). However, its main application has been in sociology (Duncan 1966, Land 1969). The technique appears in multivariate analysis texts for the social sciences such as Van de Geer (1971, pp. 112-27).

Path analysis usually begins with the construction of a path diagram. Land (1969, pp. 6-7) states that path diagrams are drawn according to the following conventions. First, the postulated causal relations among variables of the system

are represented by unidirectional arrows extending from each variable dependent on it. Second, the postulated noncausal correlations among the exogenous variables in the system are symbolized by two-headed curvilinear arrows. Residual variables are also represented by unidirectional arrows going from the residual variable to the dependent variable. Finally, the quantities entered beside the arrows are the symbolic or numerical values of the path and correlation coefficients of the postulated causal and correlational relationships.

A path model refers to the set of structural equations representing the postulated causal and noncausal relationships among the variables under consideration. Traditionally, the variables are specified in standard unit form; that is, each variable is divided by its standard deviation as well as being centered. The symbolic form of the path coefficient is p_{ij} , where the first subscript i denotes the dependent variable and the second subscript j denotes the variable whose determining influence is under consideration.

The path diagram for the earlier example involving life satisfaction among elderly consumers is

The corresponding path model is

$$x_4 = p_{43}x_3 + e_4 \quad (14)$$

$$x_6 = p_{61}x_1 + p_{63}x_3 + p_{64}x_4 + e_6 \quad (15)$$

The next step in path analysis is to multiply through each equation in the model by a predetermined variable in the equation, take expected values, and express the result in terms of path coefficients and correlations. For instance, application of this procedure to the x_4 equation yields

$$E(x_1x_4) = p_{43} E(x_1x_3) + E(x_1e_4). \quad (16)$$

Earlier the exogenous variables were assumed to be independent of the disturbances so that $E(x_i e_j) = 0$. The key is the fact the variables are in standard form. This means that $E(x_i x_j) = \rho_{ij}$, the population correlation between x_i and x_j . Our last equation becomes

$$\rho_{14} = p_{43} \rho_{13} \quad (17)$$

Similarly, we find that

$$\rho_{34} = p_{43} \quad (18)$$

Repeating this operation for the x_6 equation and estimating p_{ij} by the sample correlation, r_{ij} , we obtain

$$r_{14} = p_{43} r_{13} \quad (19)$$

$$r_{34} = p_{43} \quad (20)$$

$$r_{16} = p_{61} + p_{63} r_{13} + p_{64} r_{14} \quad (21)$$

$$r_{36} = p_{61} r_{13} + p_{63} + p_{64} r_{34} \quad (22)$$

$$r_{46} = p_{61} r_{14} + p_{63} r_{34} + p_{64} \quad (23)$$

We now could solve for the p's in terms of the r's,

$$p_{43} = r_{43} \quad (24)$$

and

$$\begin{bmatrix} p_{61} \\ p_{63} \\ p_{64} \end{bmatrix} = \begin{bmatrix} 1.0 & r_{13} & r_{14} \\ r_{13} & 1.0 & r_{34} \\ r_{14} & r_{34} & 1.0 \end{bmatrix}^{-1} \begin{bmatrix} r_{16} \\ r_{36} \\ r_{46} \end{bmatrix} \quad (25)$$

But these are the same estimates that one obtains from ordinary least squares regression (see equation 13)!

Conversely, we could solve for the r's in terms of the p's. This would permit us, where relevant, to decompose the dependent variable. One could calculate the relative contributions of the components to the variation in the dependent variable and to determine how causes affecting the dependent variable are transmitted by means of the respective intervening variables.

More specifically, the total association between two variables is given by their zero-order correlation. The total effect of one variable on another is the part of their total association which are not due to noncausal components. These noncausal components, sometimes called spurious, are due to common causes, to correlation among their causes, or to unanalyzed correlation. The total effect is composed of both direct and indirect effects. Indirect effects are effects which are transmitted or mediated by variables specified as intervening between the cause and effect under study. The direct effect is that effect which is not transmitted by means of intervening variables (Alwin and Hauser 1975).

The zero-order correlations found from manipulation of x_6 -equation can be interpreted in the following manner.

$$r_{16} = p_{16} + p_{63}r_{13} + p_{64}p_{43}r_{13} \quad (26)$$

$$.361 > .209 + (.313)(.374) + (.234)(.259)(.374)$$

$$> .209 + .117 + .023$$

The total association is r_{16} ; the direct effect, p_{16} ; the direct correlation with another cause, $p_{63}r_{13}$; the indirect correlation with another cause, $p_{64}p_{43}r_{13}$. The remainder is unanalyzed correlation. The second relationship is

$$r_{36} = p_{61}r_{13} + p_{63} + p_{64}p_{43} \quad (27)$$

$$.452 = (.209)(.374) + .313 + (.234)(.259)$$

$$= .078 + .313 + .061$$

The total association is r_{36} ; the direct effect, p_{63} ; the indirect effect, $p_{64}p_{43}$; the correlation with another cause, $p_{61}r_{13}$. The third relationship is

$$r_{46} = p_{61}p_{43}r_{13} + p_{63}p_{43} + p_{64} \quad (28)$$

$$.346 > (.209)(.259)(.374) + (.313)(.259) + .234$$

$$> .020 + .081 + .234$$

The total association is r_{46} ; the direct effect, p_{64} ; the correlation with a common cause, $p_{63}p_{43}$; the indirect correlation with another cause, $p_{61}p_{43}r_{13}$. Again, the remainder is unanalyzed correlation.

These algebraic relationships can be read directly from the path diagram according to the following rule. Read back from variable x_6 , then forward to variable x_1 , forming the product of all paths along the traverse; then sum these products for all possible traverses. In no case can one trace back having started forward. The bidirectional correlation is used in tracing either forward or back (Duncan 1966, p. 6.)

Thus, the correlation between x_3 and x_6 , r_{36} , simply equals (1) the indirect correlation with another cause (x_3), $p_{43}r_{13}$.

The correlation r_{34} is equal to (1) the direct effect, p_{43} .

The correlation r_{16} is equal to (1) the direct effect, p_{61} ;

(2) the direct correlation with another cause $p_{63}r_{13}$; (3) the indirect correlation with another cause; $p_{64}p_{43}r_{13}$. The correlation r_{63} is equal to (1) the direct effect, p_{63} ;

(2) the indirect effect, $p_{64}p_{43}$; (3) the correlation with with another cause, $p_{61}r_{13}$. Finally, the correlation r_{64} is equal to (1) the direct effect, p_{64} ; (2) the

correlation with a common cause, $p_{63}p_{43}$; (3) the indirect correlation with another cause, $p_{61}p_{43}r_{13}$.

Reading of the path diagram must be done with care. A more prudent strategy would be to depend on algebraic manipulation.

Although path analysis provides some information about the noncausal associations among variables in a system, the focus is nonetheless on the causal influences whether direct or indirect. We have already seen that direct effects can be estimated from the structural equations using econometrics. Now we will observe that the total effects can be estimated from the reduced-form equations using econometrics (Alwin and Hauser 1975). The only indirect effects in our example occur in the path $x_3x_4x_6$ which yields the effect $p_{64}p_{43}$. The corresponding direct effect between x_3 and x_6 is p_{63} . The total effect is then $p_{63} + p_{64}p_{43}$. Equation 9 shows that this total effect is given by the appropriate reduced form equation.

Conclusions

There is considerable discussion in the literature about the conditions under which to use standardized measures such as path coefficients in contrast to unstandardized regression coefficients (Tukey 1954, Turner and Stevens 1959, Wright 1960a, Blalock 1967). One participant concluded that "Path coefficients are . . . appropriate if one wishes to measure the actual amount of impact that each variable has on the others in a given population. On the other hand, unstandardized regression coefficients seem more appropriate for describing . . . causal laws." (Blalock 1967, p. 675). In any event, both sets of coefficients may be obtained by econometric means.

Although attempts have been made to extend path analysis to interdependent systems (Wright 1960b), applications have focused on recursive systems. The danger is that the models have been formulated as recursive more because of tractability than because of theoretical soundness. The errant view that only recursive systems permit causal interpretation (Strotz and Wold 1960) was long ago debunked (Basman 1963). Moreover, even where a recursive model might be the correct causal priority, the adjustment mechanism (feedback) might be rapid relative to any practical inter-measurement period. See, for instance, Farley and Lehmann (1977). Consequently, the empirical model would still be interdependent.

Path analysis adds little that is not obtainable from econometric analysis, which is more highly developed and broader in its coverage. Indeed, the founder of path analysis (Wright 1960, p. 444) was reduced to offering the following apology: "Path analysis is an extension of the usual verbal interpretation of statistics, not the statistics themselves . . . The purpose of path analysis is to determine whether a proposed set of interpretations is consistent throughout." Even the sociologists seem to be moving away from path analysis to structural equation analysis (Duncan 1975, Heise 1975). The latter seems to be an attempt to present econometric concepts without the use of matrix algebra.

Path analysis does not seem to warrant a high priority for study by buyer behaviorists. One's time would be better spent trying to understand the strengths and weaknesses of the various approaches to making causal inferences for unobservable variables (Goldberger 1974, Griliches 1974, Wold 1975, Hui and Jagpal 1979, Jagpal and Hui 1980, Jöreskog and Sorbom 1979, Bagozzi 1980).

INVESTIGATING CAUSAL SYSTEMS WITH QUALITATIVE VARIABLES:
GOODMAN'S WONDERFUL WORLD OF LOGITS

William R. Dillon, University of Massachusetts

Introduction

This paper is one of three directed at the important topic of causal modeling and its role in consumer research. The stimulating papers of my colleagues Professors Bagozzi and Parsons, appearing in this session, speak well to the issues that surface when causal systems are investigated in which the data have (continuous) quantitative components with at least interval scale properties; however, in many instances the available measurements are categorical in nature, having less than precise qualities, yet we may still wish to consider various causal hypotheses either of the temporal or nontemporal kind.

A point I would like to make early on is that in the case of ordinal data I favor the use of standard path analysis techniques. While I am fully aware that ordinal-based results can be altered by applying a suitable transformation, the Monte Carlo work suggests that violations of the interval assumption may not be very consequential, and this coupled with the fact that in most behavioral and consumer research settings the ordinal variables will generally have more than just two or three levels leads me to be more sanguine than some might be about the use of path analytic methods on ordinal scaled data.

This is not to say, however, that all caution should be discarded and that causal models of the Duncan (1966, 1975) or Wright (1960) variety be applied regardless of the distributional form of the data analyzed. Quite the contrary, the implicit or explicit assumptions of these models and methods that are violated when the variables are measured with only a small number of categories appear too severe to be ignored. Thus, if more than just heuristic or descriptive information is sought, the challenge is to find alternative approaches to modeling observable phenomena more compatible with the qualitative nature of the available responses. (The issue of unobservable variables and latent class models is also taken up in a later section.)

My remarks today are restricted to the case where the qualitative nature of the data is intrinsic to the attribute under study and not induced from some arbitrary collapsing of what would otherwise be a continuous variable. (I make this distinction since in the latter case the analysis may be best carried out by leaving the variables in their natural form and applying standard path analysis techniques.) There are a number of approaches to causal modeling with qualitative variables that are in the spirit of structural equation models; for example, Boudon (1965, 1967), Coleman (1964), Goodman (1972, 1974a), Lazarsfeld (1971) and Lazarsfeld and Henry (1968) are just a few of the social scientists who have made contributions to the area. Perhaps the closest analog to path analysis for qualitative variables is Goodman's loglinear/logit approach. Essentially, Goodman's system results in path diagrams, based on what usually is a series of logit specifications, and possesses the following attractive features:

- It provides the functional equivalent of structural equation models for qualitative data as well as the statistical tools necessary for testing.
- It is flexible in the sense of being able to handle temporal and nontemporal systems, and the case of unobservable variables.

- It can be easily implemented with currently available canned computer software packages suitable for analyzing multiway contingency tables.

The remainder of this paper represents an attempt, albeit an ambitious one, to satisfactorily do justice to the work of Goodman. While the primary intent of the piece is expository, I will attempt to address what I consider to be some interesting issues and problem areas. In preparation for the use of logit models as vehicles for investigating causal hypotheses, I begin the discussion with some basic ideas on fitting loglinear and logit models and, in addition, present the concept of spurious correlation in the context of cross-classified data.

Some Basic Ideas

This section provides the foundation for the subsequent material on causal modeling which immediately follows. My remarks will be clustered into three subsections focusing on loglinear modeling, logit specifications and the concept of spurious correlations as it relates to conditional independence-type arguments. The reader sufficiently educated in these areas is well advised to skip this material and turn to the next section which explicates Goodman's approach to causal modeling.

Loglinear Models

The most comprehensive work to date on the subject of fitting loglinear models to discrete multivariate data is the text by Bishop, Feinberg and Holland (1975). The interested reader might also wish to consult the recent text by Shelby Haberman (1978) for alternative treatments.

For illustrative purposes I will discuss the case of a four-dimensional table. However, the ideas to follow are easily generalized to lower- or higher-order tables. Let A, B, C, and D stand for the variables of interest with levels i, j, k, and l, respectively, and denote by f_{ijkl} and F_{ijkl} the respective observed and expected frequency in cell (ijkl). By expected frequency I mean the estimated count induced through fitting a specified model. If we further let n denote the total sample size, then the relationships hold that

$$\sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^K \sum_{l=1}^L f_{ijkl} = n$$

and

$$\sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^K \sum_{l=1}^L F_{ijkl} = n. \tag{1}$$

The expected value in any cell of the $I \times J \times K \times L$ table formed by variables A, B, C, D can be parametrized in multiplicative form with parameters denoted by λ , or in additive form via logarithms, with parameters denoted by μ . My preference is to use the additive form which represents F_{ijkl} as

$$\ln F_{ijkl} = \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D + \mu_{ij}^{AB} + \mu_{ik}^{AC} + \mu_{il}^{AD} + \mu_{jk}^{BC} + \mu_{jl}^{BD} + \mu_{kl}^{CD} + \mu_{ijk}^{ABC} + \mu_{ikl}^{ACD} + \mu_{jkl}^{BCD} + \mu_{ijkl}^{ABCD} \tag{2}$$

where

$$\begin{aligned} \sum_i \mu_i^A &= \sum_j \mu_j^B = \dots = \sum_k \mu_k^D = 0 \\ \sum_{ij} \mu_{ij}^{AB} &= \sum_{ik} \mu_{ik}^{AC} = \dots = \sum_{kl} \mu_{kl}^{CD} = 0 \\ \sum_{ijk} \mu_{ijk}^{ABC} &= \dots = \sum_{jkl} \mu_{jkl}^{BCD} = 0 \\ \sum_{ijkl} \mu_{ijkl}^{ABCD} &= 0. \end{aligned}$$

The right-hand side of (2) is interpretable, as in ANOVA models, in terms of individual and joint variable effects, and, consequently, has similar constraints. For completeness, it should be noted that multiplicative λ -parameters and the additive μ -terms are related by

$$\begin{aligned} \lambda &= \exp \mu; \lambda_i^A = \exp \mu_i^A; \dots; \lambda_k^D = \exp \mu_k^D; \\ \lambda_{ij}^{AB} &= \exp \mu_{ij}^{AB}; \dots; \lambda_{kl}^{CD} = \exp \mu_{kl}^{CD}; \\ \lambda_{ijk}^{ABC} &= \exp \mu_{ijk}^{ABC}; \dots; \lambda_{jkl}^{BCD} = \exp \mu_{jkl}^{BCD}; \\ \lambda_{ijkl}^{ABCD} &= \exp \mu_{ijkl}^{ABCD}, \end{aligned}$$

where "exp" denotes the exponential function. Finally, the representation given in (2) will be called a saturated model since there are as many parameters to estimate as cells in the table and, not surprisingly, the expected (or fitted) values are identical to the observed counts; that is, $F_{ijkl} = f_{ijkl}$ for all $(ijkl)$.

In almost all practical discussions the class of loglinear models is restricted to those models which satisfy the hierarchical property: If $\{\phi\}$ and $\{\phi'\}$ are any two sets of indices having the property $\{\phi\} \in \{\phi'\}$, then $\mu_{\{\phi\}} = 0$ implies $\mu_{\{\phi'\}} = 0$ and, further, if $\mu_{\{\phi'\}} \neq 0$ then all μ -term parameters containing like subscripts, that is, are a subset of $\{\phi\}$, are also not zero. Put simply, if μ_{ij}^{AB} is included in a model then the principle states that μ_i^A and μ_j^B must also be present, whereas if $\mu_{ij}^{AB} = 0$ then we must have $\mu_{ijk}^{ABC} = 0$. Given these constraints, hierarchical models can be completely defined by the minimal set of sufficient margin totals which represent the set of highest-order interactions. Adopting what I think now is standard notation, which encloses the requested model in brackets, the set of $[ABC]$, $[D]$ defines the model

$$\mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D + \mu_{ij}^{AB} + \mu_{ik}^{AC} + \mu_{jk}^{BC} + \mu_{ijk}^{ABC}, \quad (3)$$

since the presence of the margin configuration $[ABC]$ implies the presence of all its lower-order relatives.

Once the set of sufficient configurations is specified, and assuming that some of their μ -term parameters are set to zero, that is, an unsaturated model is requested, maximum likelihood estimates are readily found either directly, estimates are expressible in closed form, or through some iterative proportional fitting algorithm. Most computer algorithms use proportioned fitting whether or not direct estimates exist, and rely on a result attributable to Birch (1963) which forces maximum likelihood estimates of margin totals corresponding to specified sufficient configurations to be equal to observed marginal sums. Hence, if we specify $[AB]$ and $[AC]$ as fitted margins, then the maximum likelihood estimates of the expected frequencies obey the relationship

$$\begin{aligned} F_{ij++} &= f_{ij++} \\ F_{i+k+} &= f_{i+k+}, \end{aligned} \quad (4)$$

where f_{ij++} (F_{ij++}) and f_{i+k+} (F_{i+k+}) are the observed (expected) marginal sums derived from summing over the appropriate "+" subscripts. The degree to which the quality

of the fitted model is any good can be assessed by computing -2 times the logarithm of the likelihood-ratio test statistic used for testing that the model fitted is correct versus the unrestricted alternative. Under the hypothesis that the model is correct

$$G^2 = -2 \sum_{ijkl} f_{ijkl} \ln \frac{f_{ijkl}}{F_{ijkl}} \quad (5)$$

is asymptotically χ^2 with degrees of freedom equal to # of states - # of independently fitted parameters.

Specific hypotheses can, under this framework, be easily tested by making use of the partitioning properties of the likelihood ratio statistic and the hierarchical principle of modeling. Consider, for example, the following listing of models which represent a nested hierarchy of loglinear models:

$$\begin{aligned} (M_4) & \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D \\ (M_3) & \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D + \mu_{ij}^{AB} \\ (M_2) & \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D + \mu_{ij}^{AB} + \mu_{jk}^{BC} \\ (M_1) & \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D + \mu_{ij}^{AB} + \mu_{jk}^{BC} + \mu_{il}^{AD}. \end{aligned} \quad (6)$$

What characterizes the hierarchy is that each succeeding model differs from the model immediately preceding it by only one term. (The restriction to only one additional term is not a requirement.) Clearly, we would all agree that there is more than one set of nested hierarchical models that can be written down. For the above hierarchy denoted by $G^2(M_i)$ the likelihood ratio statistic for model M_i , then, though I omit the details, it can be shown that

$$G^2(M_4) = G^2(M_4|M_3) + G^2(M_3), \quad (7)$$

whereby $G(M_4|M_3)$ I mean the conditional likelihood ratio statistic for model M_4 given model M_3 . It follows that

$$G^2(M_4) \geq G^2(M_3) \geq G^2(M_2) \geq G^2(M_1). \quad (8)$$

If $G^2(M_4)$ and $G^2(M_3)$ are both asymptotically χ^2 random variables with degrees of freedom V_1 and V_2 respectively, then $G^2(M_4|M_3)$ is also asymptotically χ^2 with degrees of freedom $V_1 - V_2$. This property of partitioning and ordering for a nested hierarchy does not necessarily hold for the case where the Pearson statistic is used, and it is primarily for this reason that the G^2 statistic is preferred.

The conditional breakdown of G^2 into additive components is extremely useful in model building. For example, notice that the only difference between models M_4 and M_3 in the above hierarchy is the μ_{ij}^{AB} -term and, as your intuition might lead you to believe, it appears that $G^2(M_4|M_3)$ could be viewed as a test statistic for determining whether $\mu_{ij}^{AB} = 0$. (Actually, in a strict sense, we would also have to assume that variables C and D are unrelated to at least variable A or variable B in order to ensure that this test is equivalent to the test statistic used to determine whether $\mu_{ij}^{AB} = 0$ from the marginal table for variables A and B. I will have more to say about this nuance when developing the approach to causal modeling.) It is precisely in this manner that specific effects corresponding to relevant hypotheses can be tested.

Logit Specifications

In the previous discussions I made no mention of any distinctions between any of the variables. If I can assume the response variable has two levels, then it is reasonable to model the behavior of the log odds of one level of the response to the other on the basis of the explanatory variables. Upon finding a suitable log linear model, a

secondary analysis is performed and ultimately what we arrive at is a table of log odd effects from which we can better understand how changes in the combined levels of the explanatory variables affect the response measure.

To illustrate these ideas treat variable A in the $I \times J \times K \times L$ table as the response measure and the remaining variables B, C, and D as explanatory factors. In such settings we are typically interested in the relationship of the set of design or explanatory variables on the response measure. Assuming that the sample sizes for each combination of the explanatory variables are fixed by design, a little thought based on the previous discussion will show that we need to include the μ -term parameters relating the interactions between such variables in the model to insure that the estimated margin totals conform to fixed margins. Under this setup, we usually are not interested in investigating relationships between the explanatory variables but restrict ourselves to the nature of their effects on the response variables. For convenience, we can view the table as an array of rates such that

$$f_{.jkl} = f_{1jkl} / (f_{1jkl} + f_{2jkl}), \quad (9)$$

with corresponding logits given by

$$\omega_{.jkl}^{\bar{A}} = \ln(f_{1jkl} / f_{2jkl}) = \ln f_{1jkl} - \ln f_{2jkl}. \quad (10)$$

Corresponding to these observed odds, we can, in similar fashion, also define "expected odds" pertaining to variable A; that is,

$$\psi_{.jkl}^{\bar{A}} = \ln(F_{1jkl} / F_{2jkl}) = \ln F_{1jkl} - \ln F_{2jkl}. \quad (11)$$

With respect to model building and parameter estimation, we proceed essentially in the same way as was described in the previous section. The difference, as we stated, is that we must include the parameter μ_{jkl}^{BCD} in any model; in addition, suppose the best fitting parsimonious model is given by μ_{ij}^{AB} , μ_{il}^{AD} and, of course, μ_{jkl}^{BCD} . The log linear model is, therefore,

$$\ln F_{ijk\ell} = \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_\ell^D + \mu_{ij}^{AB} + \mu_{il}^{AD} + \mu_{jk}^{BC} + \mu_{j\ell}^{BD} + \mu_{k\ell}^{CD} + \mu_{jkl}^{BCD}. \quad (12)$$

The corresponding logit model is defined by

$$\begin{aligned} \psi_{.jkl}^{\bar{A}} &= \ln \frac{F_{1jkl}}{F_{2jkl}} = \\ &= [(\mu_1^A - \mu_2^A)] + [\mu_{1j}^{AB} - \mu_{2j}^{AB}] + [\mu_{1\ell}^{AD} - \mu_{2\ell}^{AD}] \\ &= 2[\mu_1^A + \mu_{1j}^{AB} + \mu_{1\ell}^{AD}] \\ &= \beta^{\bar{A}} + \beta_j^{\bar{AB}} + \beta_\ell^{\bar{AD}}, \end{aligned} \quad (13)$$

where the bar over superscript A simply is used to remind us that expected odds pertain to variable A, the dependent variable. Notice that the only interaction parameters that are included in the logit model are those terms which interact with the response variable in the corresponding loglinear specification.

We will see shortly that logit models form the basis of Goodman's approach to causal modeling. In particular, a series of logit specifications define a system of equations which are analogous to the kinds of systems of simultaneous linear equations encountered in the causal analysis of quantitative variables. Furthermore, the estimated β 's can be used to construct what are essentially path diagrams.

Spurious Correlation

Before jumping into Goodman's method for testing causal hypotheses, I would like to digress, for just a moment, in order to present a few remarks about the concept of spurious correlation when cross-classified data are analyzed. I have two reasons for doing this: first, the concept of spurious correlation is, in its own right, fundamental to the study of causal systems, and, second, a discussion of spurious correlation will, hopefully, lead to a better understanding of conditional independence type arguments used to introduce the subject of unobservable variables and latent class models.

Put simply, the association between two variables is called spurious if it vanishes in the presence of a third variable which impinges upon both. Typically, with quantitative variables, to test whether a correlation is spurious, interest centers upon the behavior of certain partial correlation coefficients. For example, a nonzero simple correlation between two variables X_2 and X_3 would be said to be spurious when upon entry of a third variable X_1 into the system, the partial correlation coefficient $r_{23.1}$ goes to zero.

In the case of qualitative variables, while we cannot couch our statements in terms of correlation coefficients, we can, nevertheless, present analogous arguments. Let us begin with the simple situation of just two variables A and B. If we now introduce a third variable C having, say, two levels, and if we find that in each of the two $I \times J$ tables formed by conditioning on the level of C, variables A and B become independent of each other, then we may say that the original relationship is spurious. In other words, we have found another variable which "explains" the relationship between variables A and B.

Similarly, if we return to our four-way table formed by variables A, B, C, D, we can say that variable D, for example, explains the relationship among the three remaining variables if the three variables A, B, C become mutually independent when the conditional relationships among the three variables in the three-way table at each level of variable D are examined. The hypothesis that variables A, B, and C are mutually independent when the level of variable C is held constant can be denoted as

$$[A \times B \times C | D]$$

where x means independent of.

The hypothesis of conditional independence can be easily tested by assessing the goodness-of-fit of the model:

$$\ln F_{ijk\ell} = \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_\ell^D + \mu_{il}^{AD} + \mu_{j\ell}^{BD} + \mu_{k\ell}^{CD}. \quad (14)$$

Notice that no μ -term parameters pertaining to the two-way interactions between the pairs AB, AC, or BC are included and, therefore, the system could be described by the following simple diagram

where the presence of an arrow indicates a nonzero effect.

Causal Analysis: The World of Logits

I will, in this section, attempt to provide an exegesis of Goodman's approach to modeling causal systems composed solely of qualitative variables. My explication of these methods and models will, for the moment, be presented in the abstract with the following section devoted to substantive examples which highlight the issues raised in the ensuing discussion.

Goodman first introduced the modification of loglinear analysis which allowed causal hypotheses to be investigated in two 1973 papers. He argued, to varying degrees throughout both pieces, that the proposed methodology produces a framework for analysis analogous to the usual analysis of causal systems with quantitative variables. Indeed, Goodman's approach can be used to study both recursive as well as nonrecursive systems, though in the latter system the analogy to the quantitative variable case is by far the weakest, and generates path diagrams much in the spirit of those obtained with systems of simultaneous linear equations. There are, however, a number of subtleties which can introduce certain ambiguities into the analysis.

This section is largely expository, and is organized around nonrecursive and recursive systems. After each major subsection, I devote some time to commending on the nuances that are inherent in Goodman's methodology.

The Analysis of Nonrecursive Systems:
The Weakest Link

I will again make use of the four-way IxJxKxL multiway table assumed generated by variables A, B, C, and D. In addition, for simplicity, assume now that I=J=K=L=2, so that the table can be described as a 2⁴ contingency table. I begin with causal modeling in nonrecursive systems, though admittedly the situation provides the weakest analogy to the analysis of systems of simultaneous linear models with quantitative variables, because without any order conditions on the variables, the use of loglinear analysis to investigate causal hypotheses will naturally lead to systems having reciprocal causation and feedback loops.

For illustrative and discussion purposes, assume that the model described by the margin totals

[AB], [AC], [BC], [BD], [CD]

provides an adequate fit to the four-way table. Recall, these margin configurations define the model

$$\ln F_{ijkl} = \mu + \mu_i^A + \mu_j^B + \mu_k^C + \mu_l^D + \mu_{ij}^{AB} + \mu_{ik}^{AC} + \mu_{jk}^{BC} + \mu_{jl}^{BD} + \mu_{kl}^{CD} \quad (15)$$

so that we would generate nonzero estimates for five two-factor interactions and four one-factor main effects. Following the notation used in the discussion of logit specifications, we could single out each variable in turn and define the expected odds pertaining to each as

$$\psi_{ijk}^{\bar{D}} = \ln F_{ijk1} - \ln F_{ijk2} \quad (16)$$

$$\psi_{ij\cdot l}^{\bar{C}} = \ln F_{ij1l} - \ln F_{ij2l} \quad (17)$$

$$\psi_{i\cdot kl}^{\bar{B}} = \ln F_{i1kl} - \ln F_{i2kl} \quad (18)$$

$$\psi_{\cdot jkl}^{\bar{A}} = \ln F_{1jkl} - \ln F_{2jkl} \quad (19)$$

where again the bar over the superscript in the ψ 's signifies that the expected odds pertain to the superscripted variable, and that these expected odds are the dependent variable in each respective formula. In similar fashion we can express (16)-(19) in terms of the logit β -effects which yields the following system of equations.

$$\psi_{ijk}^{\bar{D}} = \beta^{\bar{D}} + \beta_j^{\bar{B}\bar{D}} + \beta_k^{\bar{C}\bar{D}} \quad (20)$$

$$\psi_{ij\cdot l}^{\bar{C}} = \beta^{\bar{C}} + \beta_i^{\bar{A}\bar{C}} + \beta_j^{\bar{B}\bar{C}} + \beta_l^{\bar{D}\bar{C}} \quad (21)$$

$$\psi_{i\cdot kl}^{\bar{B}} = \beta^{\bar{B}} + \beta_i^{\bar{A}\bar{B}} + \beta_k^{\bar{C}\bar{B}} + \beta_l^{\bar{D}\bar{B}} \quad (22)$$

$$\psi_{\cdot jkl}^{\bar{A}} = \beta^{\bar{A}} + \beta_j^{\bar{B}\bar{A}} + \beta_k^{\bar{C}\bar{A}} \quad (23)$$

where we note

$$\beta^{\bar{D}} = 2\mu_{j\cdot l}^{\bar{D}}, \beta_j^{\bar{B}\bar{D}} = 2\mu_{j\cdot l}^{\bar{B}\bar{D}}, \beta_k^{\bar{C}\bar{D}} = 2\mu_{k\cdot l}^{\bar{C}\bar{D}}, \dots \text{etc.} \quad (24)$$

and, because of the assumptions imposed,

$$\beta^{\bar{B}\bar{D}} = \beta_1^{\bar{B}\bar{D}} = -\beta_2^{\bar{B}\bar{D}}, \beta^{\bar{C}\bar{D}} = \beta_1^{\bar{C}\bar{D}} = -\beta_2^{\bar{C}\bar{D}}, \text{etc.} \quad (25)$$

The meaning of equations (20)-(23) should be clear; for example, equation (20) states that the expected odds pertaining to variable D are dependent upon the explanatory variables B and C, but not upon variable A, and, according to (10) and (11), the expected odds in favor of variable D is increased when the additive effects of variable B is introduced at level 1 and decreased when variable B is at level 2.

Equations (20)-(23) provide a system of logit equations which, in spirit, are analogous to the kinds of systems of simultaneous linear equations used in the causal analysis of quantitative variables. For those of us who might be having trouble seeing the analogy, let us introduce the dummy variables X₁, X₂, X₃, and X₄, where X₁ assumes the value 1 when variable A is at level 1, 0 otherwise, X₂ assumes the value 1 when variable B is at level 1, 0 otherwise, and so on for variables X₃ and X₄ corresponding to variables C and D. We can rewrite equations (20)-(23) as a linear function of the dummy variables; for example, in the case of equation (20) we have

$$\psi_{ijk}^{\bar{D}} = \beta^* + \beta_1^* X_1 + \beta_2^* X_2 + \beta_3^* X_3 \quad (26)$$

where

$$\beta^* = \beta^{\bar{D}} - \beta^{\bar{A}\bar{D}} - \beta^{\bar{B}\bar{D}} - \beta^{\bar{C}\bar{D}} \quad (27)$$

$$\beta_1^* = 2\beta^{\bar{A}\bar{D}}, \beta_2^* = 2\beta^{\bar{B}\bar{D}}, \beta_3^* = 2\beta^{\bar{C}\bar{D}}$$

(Note, in the above formulation, $\beta^{\bar{A}\bar{D}} = 0$.)

Finally, we can extend the analogy even further by expressing the observed odds $w_{ijk}^{\bar{D}}$ in terms of the expected odds $\psi_{ijk}^{\bar{D}}$ by introducing an error component:

$$\psi_{ijk}^{\bar{D}} = \beta^* + \beta_1^* X_1 + \beta_2^* X_2 + \beta_3^* X_3 + \epsilon \quad (28)$$

where

$$\epsilon = w_{ijk}^{\bar{D}} - \psi_{ijk}^{\bar{D}} \quad (29)$$

is the error component which, unlike in the analogous regression formulation, is not independent of the expected odds.

Systems of logit equations like those defined by (20)-(23) can also be cast in path diagrams (see Figure 1). In Figure 1, the two arrows emanating from D to C and B correspond to the effects $\beta^{\bar{D}\bar{C}}$ and $\beta^{\bar{D}\bar{B}}$ in (21) and (22) respectively; the three arrows emanating from C to D, B and A

FIGURE 1
PATH DIAGRAM FOR LOGIT EQUATIONS (20) - (23)

correspond to the effects $\beta_{\overline{CD}}$, $\beta_{\overline{CB}}$, and $\beta_{\overline{CA}}$ in (20), (22) and (23) respectively; the three arrows emanating from B to D, C, and A correspond to the effects $\beta_{\overline{BD}}$, $\beta_{\overline{BC}}$, and $\beta_{\overline{BA}}$ in (20), (21), and (23) respectively; and finally, the two arrows emanating from A to C and B correspond to the effects $\beta_{\overline{AC}}$ and $\beta_{\overline{AB}}$ in (21) and (22), respectively. The absence of any arrows linking two or more variables signifies that the respective variables are not directly related. Because $\beta_{\overline{AC}} = \beta_{\overline{CA}}$, $\beta_{\overline{BC}} = \beta_{\overline{CB}}$, $\beta_{\overline{AB}} = \beta_{\overline{BA}}$, $\beta_{\overline{BD}} = \beta_{\overline{DB}}$, and $\beta_{\overline{CD}} = \beta_{\overline{DC}}$, a single double-headed arrow could be used, as Goodman does, instead of two separate single-headed arrows in the figure. I adopt the latter approach to emphasize the presence of reciprocal causation and because it has greater potential in characterizing more complex models.

Some thought concerning the system of logit specifications defined in equations (20)-(23) will show that there is more than one path diagram which is consistent with model (15). Recall in model (15) the following parameters were set to zero:

$$\mu_{\overline{AD}}, \mu_{\overline{ABC}}, \mu_{\overline{ABD}}, \mu_{\overline{ACD}}, \mu_{\overline{BCD}}, \mu_{\overline{ABCD}}$$

Comparison with Table 1, which lists the μ -terms that are set to zero for each of the specifications (20)-(23), shows that any pair of equations (20)-(23), except for the pair (21)-(22), is equivalent to model (15). Further, any triplet of equations (20)-(23) is also equivalent. Thus, a number of path diagrams can be generated, all of which are consistent with the fitted model. For example, Figures 2(a) and (b) present path diagrams for the system of equations (20)-(21). In this figure, note that there is no reciprocal causation between variables B and D, B and C, or A and C and, therefore, only one arrow is used to describe each respective relationship; whereas, as in Figure 1, the two separate arrows from C to D and from D to C correspond to the effects $\beta_{\overline{CD}}$ and $\beta_{\overline{DC}}$ in (20) and (21), respectively.

TABLE 1
THE μ -TERM PARAMETERS IN THE SATURATED MODEL SET TO ZERO IN LOGIT SPECIFICATIONS (20)-(23)

Expected Odds	Equation Number	μ -Terms Set to Zero
$\psi_{\overline{ijk}}$	(20)	$\mu_{\overline{AD}}, \mu_{\overline{ABD}}, \mu_{\overline{ACD}}, \mu_{\overline{BCD}}, \mu_{\overline{ABCD}}$
$\psi_{\overline{ij \cdot l}}$	(21)	$\mu_{\overline{ABC}}, \mu_{\overline{ACD}}, \mu_{\overline{BCD}}, \mu_{\overline{ABCD}}$
$\psi_{\overline{i \cdot k l}}$	(22)	$\mu_{\overline{ABC}}, \mu_{\overline{ABD}}, \mu_{\overline{BCD}}, \mu_{\overline{ABCD}}$
$\psi_{\overline{jk l}}$	(23)	$\mu_{\overline{AD}}, \mu_{\overline{ABC}}, \mu_{\overline{ABD}}, \mu_{\overline{ACD}}, \mu_{\overline{ABCD}}$

Figures 2(a) and (b) are the same except for the stated relationship between variables A and B. The distinction comes about because although the $\mu_{\overline{AB}}$ -term parameter is included in model (15), there is no logit parameter counterpart specified in either (20) or (21). This means that there are no arrows emanating from variables C or D to variables A or B and my preference is to view variables A and B as "exogenous" as opposed to "endogenous" variables. However variables A and B are viewed, their relationship can be assessed by collapsing over the other endogenous variables, C and D, and analyzing the resulting two-way table. To distinguish β -effects estimated from condensed tables as opposed to those derived from complete tables, I will use a double-headed curved arrow and enclose the coefficient in parentheses as shown in Figure 2(a). That is, in the figure the double-headed curved arrow shown in part (a) signifies that, based upon the [AB] marginal table, variables A and B are not statistically independent, as contrasted to part (b) where the absence of any arrow(s) connecting variables A and B signifies that, based upon the reduced two-way table, variables A and B are statistically independent.

FIGURE 2
PATH DIAGRAM FOR LOGIT EQUATIONS (20)-(21)

a) Mutual dependence between variables A and B

b) Mutual independence between Variables A and B

Comment. Figures 1 and 2 both describe nonrecursive causal models in the usual sense that at least one pairwise relationship in each figure is characterized by two single-headed arrows which signifies reciprocal causation. With four quantitative variables $Z_1, Z_2, Z_3,$ and Z_4 the following structural equations define a nonrecursive system:

$$Z_3 = \beta_{31}Z_1 + \beta_{34}Z_4 + \epsilon_3, \quad (30)$$

$$Z_4 = \beta_{42}Z_2 + \beta_{43}Z_3 + \epsilon_4, \quad (31)$$

where ϵ_3 and ϵ_4 are random disturbance terms with zero means. Notice that in (31) variable Z_3 , which appeared as a dependent variable in (30), appears as an independent variable used to explain variable Z_4 . In the above set up, the "causal effects" of Z_4 on Z_3 can differ (in magnitude) from the "causal effects" of Z_3 on Z_4 ; that is, there is no restriction that $\beta_{34} = 1/\beta_{43}$. On the contrary, in the Goodman approach, the reciprocal effects are by necessity equal to one another. This is particularly troublesome, and while I could suggest that one fit logit models separately (independent to the complete table), which will induce unequal estimates of the reciprocal effects, this procedure is not totally satisfactory since it seems to ignore the fundamental simultaneity of the models.

Goodman (1973b) states, in closing the section on nonrecursive systems, that while the techniques required for the analysis of nonrecursive systems when the variables are quantitative are usually more complicated than are those required for a corresponding analysis of recursive systems, when the variables are qualitative the methods and models derived from considering loglinear analysis are as easily applied to nonrecursive as well as recursive systems. Though the ease of application cannot be denied, we will see very shortly that polytomous variables and/or the presence of higher-order effects can render the analysis

complex. In addition, the multiplicity of path diagrams that are consistent with a given model means that a great deal of burden is placed on the analyst, and this, coupled with the fact that certain effects will be estimated from collapsed tables and others from the complete table, leads me to suggest that the technique be applied carefully so as to avoid misleading results. (I return to the issue of collapsing tables and the problem of path coefficients in the next section.)

Analysis of Recursive Systems

Let us return once again to our four-way table consisting of variables A, B, C, and D, each having two levels. If I impose order conditions such that variable A is causally prior to variable B, variable B causally prior to variable C, and variable C causally prior to variable D, then, under this setup, reciprocal causation and feedback loops have been ruled out. This assumed causal ordering would also seem to imply that any path diagram should be based on three (logit) models: (1) B given A, (2) C given A and B, and (3) D given A, B, and C, which when combined characterizes the conditional joint probability of B, C, and D, given A.

Suppose, on the other hand, that the true causal ordering is variables A and B are causally prior to variable C, and all three variables are prior to variable D. Under this setup Goodman would recommend that one first develop a model for the [AB] marginal table; call this model M_1 . The relationship between variables A and B would be assessed on the basis of the usual likelihood ratio χ^2 statistic based upon the condensed table. Next, attention would be focused on the three-way table [ABC] and models would be fit which included in the set of fitted margins the [AB] margin total; call this selected model M_2 . Finally, consider a model M_3 for the complete four-way table [ABCD] which contains the margin total [ABC] in the set of fitted margins.

Goodman (1973a, 1973b) shows that, under the assumption that the models M_1 , M_2 , and M_3 are all true, the test for the combined model, call it M^* , can be calculated by either estimating the expected frequencies from those obtained under M_1 , M_2 , and M_3 or by the partitioning property of the likelihood ratio χ^2 statistic. In the former case, note

$$F_{ijk\ell}^* = F_{ij}^f F_{ijk}^f / F_{ijk\ell}^f \quad (32)$$

where $F_{ijk\ell}^*$ denotes the expected frequencies under M^* , and thus the $F_{ijk\ell}^*$ can then be substituted into the formula for the likelihood ratio χ^2 statistic and the appropriate test performed. Alternatively, in the latter case, note that, because of the simple multiplicative form of the expected frequencies shown in (32), we have

$$\chi^2(M^*) = \chi^2(M_1) + \chi^2(M_2) + \chi^2(M_3), \quad (33)$$

with the degrees of freedom for M^* equaling the sum of the degrees of freedom for the separate χ^2 statistics for M_1 , M_2 , and M_3 .

The path diagram for this model is presented in Figure 3. We see from the figure that: (a) variable D is posterior to the other variables since there are no arrows pointing from D to any of the other variables; (b) the arrows emanating from variables B and C to variable D reflect the situation found in equation (20), namely,

$$\psi_{ijk}^D = \beta_j^D + \beta_j^{BD} + \beta_k^{CD}, \quad (34)$$

and correspond to β_j^{BD} and β_k^{CD} , respectively; and, finally, (c) variable B is statistically independent of variable C, given the level of variable A.

FIGURE 3
PATH DIAGRAM FOR LOGIT EQUATIONS (34)-(39)

The β_i^{AB} and β_j^{BA} effect parameters are induced from fitting the saturated model to the condensed [AB] marginal table; viz.:

$$\ln F_{ij}^{AB} = \mu + \nu_i^A + \nu_j^B + \nu_{ij}^{AB}, \quad (35)$$

which generates the logits

$$\psi_i^B = \beta_i^B + \beta_i^{AB}$$

and

$$\psi_j^A = \beta_j^A + \beta_j^{BA}. \quad (36)$$

The conditional independence of variables B and C given the levels of variable A, that is, $[B \times C | A]$ can be expressed in a form which resembles equation (21). Letting F_{ijk} denote the expected frequency in cell (i,j,k) of the marginal table [ABC], the expected odds with respect to variable C at the joint level (i,j) on variable (A,B) are given by:

$$\begin{aligned} \psi_{ij}^C &= \ln F_{ij1} - \ln F_{ij2} \\ &= \beta_i^C + \beta_i^{AC}. \end{aligned} \quad (37)$$

Comments. Some reflection on Figure 3 might lead one to consider fitting the following loglinear model to the complete four-way table: [AB], [AC], [BC], [BD], [CD], where each two-factor effect corresponds to each arrow in the path diagram. However, though this loglinear model is consistent with the figure, it ignores the hypothesized structure among the variables and, in general, effect estimates derived from a single loglinear model fitted to the complete table will differ from those induced from considering a series of logit models.

On the other hand, collapsing variables may require that certain parameters be fitted that otherwise would have been set to zero if the full table had been analyzed; that is, it is not too uncommon to find that, say, in the condensed [ABC] table, the two-factor effect [BC] is needed (the model of conditional independence of variables B and C does not fit well), whereas in the next stage this effect is nil in that the model [ABC], [AD], [BD], [CD] provides an adequate fit. In fact, several of the examples used by Goodman exhibit the property. For instance, in Goodman (1973a) a four-way table relating the attitudes of school children is analyzed and various path diagrams based on the model M^* : [AB], [AC], [BC], [BD], [CD] are discussed. However, as Goodman admits, the simpler model, M^{**} : [AC], [BC], [BD], [CD], which does not fit the [AB] margin total, also fits the data quite well. If we follow Goodman's approach this term must always be included since the effect is estimated from the collapsed [AB] table.

In the preceding two paragraphs I have attempted to play the devil's advocate by arguing that, on the one hand,

fitting a single loglinear model to a complete table ignores the structure among the variables as evinced by a series of logit models, while, on the other hand, collapsing a variable may require one to fit parameters that would be unnecessary (if the complete table was analyzed). Though each argument has merit, I prefer to follow the hypothesized causal ordering of the variables and allow the reduced tables to dictate the effect parameters included, even in the face of including "additional" parameters. Further, I would argue that when causal priorities are imposed among the variables, the complete multiway table should only be analyzed in the context of the hypothesized relationship between the antecedent and posterior variable(s).

The final point that I wish to make relates to the path coefficients themselves. Though I will insert coefficients corresponding to β -effect values into the path diagrams presented in the following section, there is no formal calculus of these coefficients as exists in analysis of qualitative variables. Consequently, it is difficult to decide what values to assign to arrows not explicitly accounted for by the system of logits, and anything other than "direct" effects is difficult to assess.

Illustrative Examples

I will now devote some effort to showing two different examples of how the methods and models of Goodman can be used in modeling causal systems. Both examples deal with recursive systems. (My earlier remarks support this selection.) The examples are, however, different: the first example is rather straight-forward yet amply illustrates the basic features of the analysis of recursive systems discussed in the previous section; the second example is intended to demonstrate some of the difficulties encountered when polytomous variables and higher-order interactions are present.

Example 1

My first example will analyze data collected in a survey of 2409 individuals on their preference for a particular branch of savings institutions. The data are displayed in Table 2; the table cross-classifies each individual according to four dichotomous (Yes, No) variables: (a) whether the person is familiar with the branch, (b) the person's opinion whether the branch is conveniently located, (c) prior experience (patronage) with the branch, and (d) whether the person strongly recommends the branch.

One plausible causal ordering is that A and B precede C and D; that is, familiarity with and opinions concerning locational convenience are antecedent to one's having previously patronized the branch, and all three affect whether a person would strongly recommend the branch. I view both variables A and B as antecedent to variable C since it is difficult to argue that one precedes the other, and I prefer to treat each as simply exogenous. The relationship between variables A and B was assessed in the condensed [AB] marginal table shown in part (b) of the table. Simple computation shows the cross product ratio $\alpha = 2.7 (485 \times 1037 / 240 \times 547)$. Since an $\alpha = 1$ is consistent with the hypothesis of independence between A and B, we conclude that A and B are positively related. (We could, of course, compute a G^2 statistic and test its significance but given the magnitude of α this seems unnecessary.)

Next, prior experience, variable C, is treated as the response measure and variables A and B as explanatory. With margin total [AB] fixed (the [AB] margin proved significant) there are three unsaturated loglinear models corresponding to such a logit model:

TABLE 2
CROSSCLASSIFICATION OF FAMILIARITY (A), LOCATIONAL CONVENIENCE (B), PREVIOUS PATRONAGE (C) AND STRENGTH OF RECOMMENDATION*

(C)	(D)	(B)	1.0	A	2.0
1.0	1.0	1.0	423		187
		2.0	459		412
2.0	2.0	1.0	49		47
		2.0	68		127
	1.0	1.0	13		84
		2.0	17		407
2.0	1.0	1.0	0		22
		2.0	3		91

Part (a) [AB] Marginal Table

(B)	1.0	A	2.0
1.0	485		340
2.0	547		1037

Part (b) [ABC] Margin Table

(C)	(B)	1.0	A	2.0
1.0	1.0	472		234
	2.0	527		539
2.0	1.0	13		106
	2.0	20		498

* Variable A is whether the person is familiar with the branch; variable B is the person's opinion whether the branch is conveniently located; variable C is whether the person had previously patronized the branch; and variable D is whether the person strongly recommends the branch. The first level of each variable reflects a positive answer, the second level a negative one.

- M_1 : [AB] [AC] [BC] (1 d.f.; $G^2 = 1.01$)
 M_2 : [AB] [AC] (2 d.f.; $G^2 = 31.02$)
 M_3 : [AB] [BC] (2 d.f.; $G^2 = 533.84$)

Clearly, the only one of these models that provides an adequate fit to the data is model M_1 . Model M_1 posits no second order interactions and corresponds to the logit model

$$\psi_{ij}^{\bar{C}} = \beta_{\bar{C}} + \beta_i^{\bar{A}\bar{C}} + \beta_j^{\bar{B}\bar{C}} \quad (38)$$

The respective estimated effect parameters are 1.53 and 0.33.

The final step is to build a logit model treating variable D, whether the person strongly recommends the brand, as the dependent variable and the other three variables as explanatory. There are eight unsaturated loglinear models, each of the three two-factor effects may be absence or presence. Four of these models are listed below:

- M_4 : [ABC] [AD] [BD] [CD] (4 d.f.; $G^2 = 4.45$)
 M_5 : [ABC] [BD] [CD] (5 d.f.; $G^2 = 39.86$)
 M_6 : [ABC] [AD] [CD] (5 d.f.; $G^2 = 6.24$)
 M_7 : [ABC] [AD] [BD] (5 d.f.; $G^2 = 8.19$)

Models M_4 and M_6 provide reasonable fits to the data while models M_5 and M_7 are unacceptable. Since Model M_6 differs from model M_4 in only one term, [BD], a test for the significance of this effect can be accomplished by simply taking the difference in the G^2 statistics associated with each and then comparing this value to a χ^2 distribution with 1 d.f. Noting that $G^2(M_6) - G^2(M_4) = 1.79$, which is nonsignificant, the preference is for Model M_6 . The

corresponding logit is

$$\psi_{ijk}^{\bar{D}} = \beta_{\bar{D}} + \beta_i^{\bar{AD}} + \beta_k^{\bar{CD}} \quad (39)$$

The effect estimates are 0.39 and -0.12, respectively.

The path diagram characterizing this system is shown in Figure 4. Notice I use the double-headed curved arrow to indicate that no decision as to whether A causes B or B causes A has been made and have enclosed the corresponding effect-estimates in () to emphasize that these variables are viewed as exogenous to the system. The causal interpretation of Figure 4 is that the exogenous variables, branch familiarity and opinions concerning its locational convenience, are related; these variables, familiarity and locational convenience, affect prior patronage; and whether the branch received a strong recommendation is affected by familiarity and prior patronage. Interestingly, the β -effect associated with prior patronage and recommendation ($\beta^{\bar{CD}}$) is negative which implies that previous experience with the branch decreases the likelihood of the branch receiving a strong recommendation. It seems, unfortunately, that the old adage: familiarity (in the form of prior contact) breeds contempt, does actually hold.

FIGURE 4
PATH DIAGRAM SHOWING CAUSAL CONNECTIONS
IMPLIED BY LOGIT MODELS (38)-(39)

Note, finally, that if we were not concerned with the hypothesized structure among the variables as expressed in terms of logit specifications, the system shown in Figure 4 might lead us to fit the loglinear model:

$$M_8: [AB] [AC] [AD] [BC] [CD]$$

to the four-way table, where each arrow in the figure is represented by a two-factor effect. The G^2 statistic for this model has a value of 7.25 with 6 d.f. Hopefully, most of us can now understand why this value is identical to the numerical value obtained from the pair of recursive logits; that is if the G^2 statistic corresponding to the combined recursive system by G_*^2 then we have:

$$G^2(M_8) = G_*^2 = G^2(M_4) + G^2(M_6)$$

$$7.25 = 7.25 = 1.01 + 6.24.$$

Example 2

The next example makes use of data, originally collected by Sewell and Shah (1968), on the relationship among five variables: (A) socioeconomic status (high, upper middle, lower middle, low), (B) intelligence (high, upper middle, lower middle, low), (C) sex (male, female), (d) parental encouragement (low, high), and (E) college plans (yes, no). The five-way table is shown in Table 3. The data present

		High	28	72	142	360	
	No	Low	96	113	81	49	
		High	24	50	77	98	

a number of problems not previously illustrated, namely, polytomous variables and logit models that will include second-order effects. I note that this example has been analyzed elsewhere and my discussion will follow Fienberg's (1977) analysis.

A causal model proposed by Sewell and Shah specifies

A
and
B precede D precedes E;
and
C

two logits characterize the system where in one socioeconomic status, intelligence and sex are viewed as antecedent, exogenous variables to parental encouragement; while in the second, college plans is the response measure and all four remaining variables are treated as explanatory. With respect to the exogenous variables A, B, and C, the only reasonably fitting model included all three two-factor effects: [AB], [AC], [BC] (9 d.f.; $G^2 = 11.50$). We thus conclude that socioeconomic status is associated with intelligence and with sex, and intelligence and sex are also positively related. Again we do not distinguish between any of these causal orderings.

Treating, first, variable D, parental encouragement as the response measure, some plausible logit models are:

- M₁: [ABC] [AD] [BC] [CD] (24 d.f.; G² = 55.81)
- M₂: [ABC] [ABD] [CD] (15 d.f.; G² = 34.60)
- M₃: [ABC] [BCD] [ACD] (18 d.f.; G² = 31.48)
- M₄: [ABC] [ABD] [BCD] (12 d.f.; G² = 22.44)
- M₅: [ABC] [ABD] [ACD] (12 d.f.; G² = 22.45)
- M₆: [ABC] [ABD] [ACD] [BCD] (9 d.f.; G² = 9.22)

The only model providing an acceptable fit is model M₆ which included three second-order effects. The logit counterpart to model M₆ is

$$\psi_{ijk}^{ABCD} = \beta^{\bar{D}} + \beta_i^{A\bar{D}} + \beta_j^{B\bar{D}} + \beta_k^{C\bar{D}} + \beta_{ij}^{AB\bar{D}} + \beta_{ik}^{AC\bar{D}} + \beta_{jk}^{BC\bar{D}} \quad (41)$$

The presence of second-order effects presents no real problem, except they are, of course, more complex, but we have yet to consider path diagrams induced from such effects.

Next, variable E, college plans, becomes the response measure. Some plausible logit models are

- M₇: [ABCD] [E] (63 d.f.; G² = 4497.51)
- M₈: [ABCD] [AE] [BE] [CE] [DE] (55 d.f.; G² = 73.82)
- M₉: [ABCD] [BCD] [AE] [DE] (52 d.f.; G² = 59.55)
- M₁₀: [ABCD] [BCD] [ACE] [DE] (49 d.f.; G² = 57.99)

Both models M₉ and M₁₀ provide acceptable fits. For reasons of parsimony (and since the difference in G² values of these two models is nonsignificant) model M₉ is selected; the corresponding logit is:

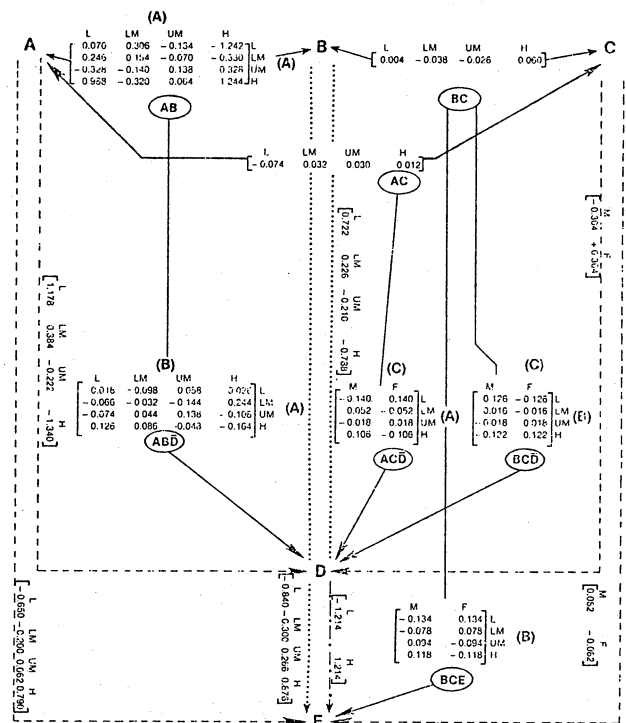

$$\psi_{ijkl}^{ABCDE} = \beta^{\bar{E}} + \beta_i^{A\bar{E}} + \beta_j^{B\bar{E}} + \beta_k^{C\bar{E}} + \beta_l^{D\bar{E}} + \beta_{ik}^{BC\bar{E}} \quad (42)$$

Note, this model includes one second-order effect corresponding to the effects of intelligence and sex on college plans, and two first-order effects which show that college plans are affected by socioeconomic status and parental encouragement.

Though a simple path diagram like those presented earlier is not possible, a diagrammatic representation, albeit more complex, of the induced logit system is possible. Consider Figure 5 which portrays the path diagram showing the causal connections implied by models M₆ and M₉. In the figure, (---) lines pertain to variable A, (····) lines to variable B, (— — —) lines to variable C, and (— · — · —) lines to variable D; association between the exogenous variables is shown by double-headed curved arrows and higher-order effects are shown by a solid single-headed arrow which emanates from the effect in question. Path coefficient effects have been included, where column and row headings have been inserted to identify particular effects.

The first order effect estimates for variables A, B, and C are in the expected direction. The likelihood of low versus high parental encouragement decreases monotonically as we move from low to high socioeconomic status and intelligence, and it seems males get more encouragement than females. The second-order effects of sex by intelligence show low intelligent males receiving relatively less encouragement than low intelligent females and high intelligent males receiving relatively more than high intelligent females; the second order effects of sex by socioeconomic status shows males receiving less parental encouragement than their female counterparts. With respect to college plans, the first order effects indicate that there are positive affects on college plans from being male, of high socioeconomic status, or of high intelligence. Notice the monotonic order to the effect estimates within the socioeconomic and intelligence categories. The second-order effects between sex and intelligence are also monotonically ordered with males having low intelligence less likely to

FIGURE 5
PATH DIAGRAM SHOWING CAUSAL CONNECTIONS
IMPLIED BY LOGIT MODELS (41)-(42)

Variable A is socioeconomic status (high, upper middle, lower middle, low), variable B is intelligence (high, upper middle, lower middle, low), variable C is sex (male, female), variable D is parental encouragement (low, high) and variable E is college plans (yess, no).

plan for college than a female with comparable intelligence, whereas the obverse is true for males and females with high intelligence.

Latent Class Models

I have already introduced the concept of spurious correlation with qualitative variables. The approach taken in that section was to argue that the association between two variables is spurious if it vanishes in the presence of a third variable which impinges upon both. In the context of our illustrative four-way table we said if three variables, say, A, B, and C, become mutually independent when the levels of the remaining variable, D, are controlled for, then their original relationship is spurious.

Consider the situation where some other variable, say, variable X, not part of the original cross-classification, can explain the relationships among the four variables when this new variable is controlled for. Once one accepts the possibility of some "outside" factor affecting the apparent relationship among the system variables, the step to considering latent class models is a rather easy, direct one since one need only assume that the explanatory variable in question is unobservable (or latent).

The situation described in the preceding paragraph can be diagrammed as

where A, B, C, and D are the observable (manifest)

variables and variable X is the explanatory latent variable. To model this relationship, let p_{ijkl} denote the observed proportion (probability) of individuals in cell (i,j,k,l) where

$$P_{ijkl} = f_{ijkl}/n. \quad (43)$$

For some specified hypotheses about the system of variables in the four-way table let π_{ijkl} be the expected proportion of individuals in cell (i,j,k,l) where the relationship holds that

$$F_{ijkl} = n\pi_{ijkl}. \quad (44)$$

Assume further that variable X has t latent classes so that π_t^X denotes the probability that an individual will be in class t and π_{ijklt}^{ABCDX} denotes the probability that an individual will be at level (i,j,k,l,t) with respect to the joint variable (A,B,C,D,X). Letting $\pi_{it}^{\bar{A}X}$, $\pi_{jt}^{\bar{B}X}$, $\pi_{kt}^{\bar{C}X}$, and $\pi_{lt}^{\bar{D}X}$ be conditional probability that an individual will be at level i with respect to variable A, level j with respect to variable B, etc., given that s/he is at level t on variable X then we can express the hypothesized system as

$$\pi_{ijklt}^{ABCDX} = \pi_t^X \pi_{it}^{\bar{A}X} \pi_{jt}^{\bar{B}X} \pi_{kt}^{\bar{C}X} \pi_{lt}^{\bar{D}X}, \quad (45)$$

and

$$\pi_{ijkl} = \sum_t \pi_{ijklt}^{ABCDX}. \quad (46)$$

Formula (45) simply states that the latent variable explains the relationships among the manifest variables in the sense that any relationships disappear (the manifest variables are mutually independent) when the latent variable X is held constant. It is very easy to see how path diagrams based on logit models of the form previously discussed can be used in the analysis of latent class models by simply defining $\omega_{jkl}^{\bar{A}}$ as the odds that an individual will be at level 1 rather than level 2 on variable A given his joint level on the remaining variables (B,C,D,X) is (j,k,l,t); i.e.,

$$\omega_{jkl}^{\bar{A}} = \pi_{1jkl}^{\bar{A}BCDX} / \pi_{2jkl}^{\bar{A}BCDX} \quad (47)$$

However, from (45) we have

$$\omega_{jkl}^{\bar{A}} = \pi_{1t}^{\bar{A}X} / \pi_{2t}^{\bar{A}X} \quad (48)$$

since the hypothesis under study is that the expected odds pertaining to variable A are affected by the level of variable X, but not by the level (j,k,l) of the other variables (B,C,D).

Due to space constraints I will say no more about this class of models. However, at this point, the reader should be able to see the approach that Goodman will take in the analysis of such systems: Various loglinear models are fitted which describe the relationships among the manifest variables when one or more latent variables are controlled for. Corresponding logits are then formed with the estimated effect parameters inserted as coefficients in the path diagram. The interested reader wanting further details, especially with respect to maximum likelihood estimation, should consult Goodman (1974a, 1974b).

Concluding Remarks

I have restricted my remarks to the use of loglinear model in the analysis of causal systems, and specifically to the work of Goodman. In doing so, I have no doubt slighted many. For example, Bahadur (1961), Boudon (1968), Coleman (1964), and Davis (1974, 1975) are just a few of those who have made important contributions in the area. The work of Davis (1975) is particularly noteworthy in that he

describes an interesting way of modeling cross-classified data which utilizes linear flow graphs based on differences in proportions instead of odds ratios. Even with respect to the methods and models championed by Goodman I have been remiss. Model testing, parameter estimation, and the whole class of latent models have only been superficially covered.

Critics of Goodman's system might cite me for not being more critical of his approach. After laboring through Goodman's papers several times (this itself is, I think, a major feat--reading Goodman can overwhelm one, especially his footnotes) I believe his system to be sound, if, of course, care and good judgment on the part of the user are exercised. Critics have been quick to point to situations where the analogy to the analysis of quantitative variables via systems of linear simultaneous equations is the weakest, namely: (1) the absence of a calculus for the path coefficients and (2) the problems caused by polytomous variables and higher-order effects. We have seen, however, that point (2) presents no serious problems; in particular, Example 2 demonstrated that path-like diagrams, although admittedly more complex, can be constructed in such a way as to convey the character of the causal system under study. With regard to point (1) the situation is, unfortunately, more serious. Because the Goodman approach does not impose a structure analogous to the usual normal equations and since the ψ 's do not actually become independent variables in succeeding logit specifications, the Wright multiplication theorem does not operate. Nevertheless, I see no reason why the estimated β -effects cannot be inserted in the path diagram for they serve a very important interpretive purpose. The user who, for whatever reasons, wants to employ Wright-like multiplication rules when analyzing qualitative data, especially in the case of dichotomous variables, should refer to the methods and models proposed by Boudon (1965) and Davis (1975).

The other uncomfortable feature of Goodman's approach relates to the multiplicity of loglinear models that can be fitted which are consistent with a given series of logit specifications. This, as I have indicated, places an extreme burden on the analyst. Yet this burden may well be a blessing in the sense that it can possibly provide the motivating force leading one to rely on theoretical arguments in order to generate explicit causal orderings among the variables. It is in situations where the hypothesized causal system is induced from theory that the methods and models proposed by Goodman work best; without theory to guide us, I'm afraid, the intent of most studies, no matter what the form of analysis, becomes explanatory and often subject to Procrustes-like solutions.

ATTRITION BIAS IN THE ESTIMATION OF
ECONOMETRIC MODELS FROM PANEL DATA

Russell S. Winer, Columbia University

Abstract

Panel data are often used to estimate the parameters of econometric or other linear models. However, a common problem with panel data is attrition. In this paper, a model is developed that corrects structural econometric models estimated using panel data for possible attrition bias. The model is illustrated using a simultaneous equation structural model and panel data that have an attrition problem. The results indicated that the impact of attrition tended to be on the model's exogenous variables and not on the endogenous variables that were exogenous in the equations.

Introduction

Researchers in marketing and other social science disciplines often conduct studies where a sample of individuals is interviewed at two or more points in time. Such data have been referred to in various literatures as longitudinal, cross-sectional, time-series and panel. To marketing researchers, the term panel data usually connotes consumer panel data which are records of household purchasing behavior over time. However, panel studies other than those using consumer panel data have occurred frequently in the marketing literature.

Although panels have been widely used, they are not without problems (Carman 1974). One of these problems is panel attrition or mortality. Except for panels operating under tightly controlled conditions, panel attrition is unavoidable. For example, Charlton and Ehrenberg (1976) report that 88% of their initial sample completed the 25-week panel. The panel utilized by Farley, Howard, and Lehmann (1976) exhibited a 43% drop-out rate over four waves of interviewing spanning fifteen months.

There has been considerable interest in the possibility of panel bias occurring due to attrition. For example, in a panel study of economic attitude study and change covering the years 1954-1957, Sobol (1959) found that renters, people with low income, and people disinterested in the study tended to drop out. Bucklin and Carman (1967) also found the interest factor and its correlates to be highly related to attrition. Ferber (1966) discovered disproportionately high attrition rates related to older age, lower education, self-employment, and high personal asset value. Therefore, assuming an initial probability sample or an alternative sampling approach attempting to represent the population studied, the sample left at the end of the final wave may be biased with respect to the population.

Econometric or other linear models have often been used to analyze panel data. Such applications have been in the areas of evaluating advertising effectiveness (Prasad and Ring 1976, Winer 1980), market segmentation (Frank, Massy, and Boyd 1967, McCann 1974), testing general models of buyer behavior (Farley and Ring 1970, Farley, Howard, and Lehmann 1976), sales management (Futrell and Jenkins 1978), and others.

The effect of attrition on the parameters of linear models has been ignored in studies using panel data. This paper describes the conditions under which parameter bias can occur from attrition and develops a model to correct for the bias. It is demonstrated that the bias is actually specification error in the structural model being estimated.

The model correcting for attrition bias simultaneously determines the correlates of attrition and the structural model parameters. The model is estimated using panel data exhibiting attrition.

Attrition Effects On Regression Estimates

Overview

It is assumed that everyone on the panel, both attriters if they were observed and non-attriters, follow the same linear model in any given wave,

$$y = \chi \beta + \epsilon, \quad (1)$$

where

- y = $N \times 1$ vector of observations on the dependent variables;
- χ = $N \times k$ matrix of independent variable observations;
- β = $k \times 1$ vector of coefficients;
- ϵ = $N \times 1$ vector of normal disturbances, $\sim N(0, \sigma_\epsilon^2)$

That is, if they could be observed, the behavior of the dropouts is not different from the people remaining on the panel. Attriters could differ, of course, in the χ matrix but not in terms of β . If β differed between attriters and non-attriters, no correction in a non-attriter model could ever be made and population inferences from a sample experiencing attrition could not be done.

If attrition probability is a function solely of χ or is random, no bias of β is induced. There is, however, some loss of efficiency (i.e., the coefficient standard errors will be larger than they should be) since there is a decline in the working sample size. On the other hand, bias will exist in β if the probability of attrition is related to y and, hence, ϵ . Since it is known that interest in the study is a determinant factor in the mortality problem, it is possible that a correlate of interest is a prospective dependent variable of a structural model. For example, if behavioral measures such as awareness and attitude are being tracked over time for a product, families continuing to lack knowledge about the product may be more likely to drop out than those that are familiar with it. That the bias exists is demonstrated by the figure:

FIGURE 1
Effects of Dependent Variable-Related Attrition

An implication of this discussion is related to panel operation. For some panels such as commercial consumer panels, households that attrite are replaced by other households. It is clear that the primary criterion for using a family as a replacement should be in terms of a potential dependent variable such as purchasing rather than description variables such as family size, sex, income, etc., if linear models are to be used in analyzing the data. Replacement by household descriptors will cause the sample to resemble the population from which the original panel was drawn but does not cause the bias in β to vanish.

A Model of Attrition

To formalize the above discussion recent papers in the economics literature will be drawn upon. Hausman and Wise (1976, 1977, 1979), Heckman (1976), and Griliches, Hall, and Hausman (1977) have all developed models for dealing with the general problem of incorporating non-random missing data into econometric analysis of panel data of which attrition is a special case. Samples from which attrition has occurred are termed censored; in truncated samples, no data at all are available on a group of households as they were systematically excluded. Since data are available for panel dropouts, the probability that an observation is in the sample can be computed from censored samples. That is not the case for truncated samples. This probability is an important part of correcting the structural equation (1) for possible attrition bias.

Model Development

Again, consider equation (1), $y = \chi\beta + \epsilon$, to be the structural model for the panel members for a given wave. Let $D = 1$ if y is observed for a panel member, and let $D = 0$ if y is unobserved due to attrition. Assume that y is observed ($D = 1$) if

$$d = \alpha y + X\gamma + W\theta + \mu \geq 0, \quad (2)$$

where y and X are as before and

$W = n \times m$ matrix of variables that do not affect y but affect the probability of its being observed;

$\alpha, \gamma, \theta =$ scalar, $k \times 1$, and $m \times 1$ vectors of parameters,
 $\mu \sim N(0, \sigma_\mu^2)$

The inequality could be relative to any threshold value but is set ≥ 0 for convenience. The vector, θ , could be all zeros. If (1) is substituted into (2), the result is

$$\begin{aligned} d &= \alpha (X\beta + \epsilon) + X\gamma + W\theta + \mu \\ &= X(\alpha\beta + \gamma) + W\theta + \alpha\epsilon + \mu. \end{aligned} \quad (3)$$

A reduced form of (3) is

$$d = X\pi + W\theta + \delta. \quad (4)$$

It follows that

$$\text{prob}(d \geq 0) = \text{prob}(D=1) = F\left(\frac{X\pi + W\theta}{\sigma_\delta}\right) \quad (5)$$

$$\text{prob}(d < 0) = \text{prob}(D=0) = 1 - F\left(\frac{X\pi + W\theta}{\sigma_\delta}\right)$$

where $F(\cdot)$ is the standard normal distribution function.

As discussed in the previous section, $E(\epsilon)$ may not equal zero since some y values and, hence, errors are truncated when attrition occurs. Given the structural equation (1) and the equation describing the probability of being in the sample, equation (4), then

$$E(y|X, D=1) = \chi\beta + E(\epsilon|X, D=1). \quad (6)$$

of interest is $E(\epsilon|X, D=1)$. Since a y -observation, and, hence, ϵ , exists only if $d \geq 0$, the error can be re-written

$$E(\epsilon|X, D=1) = E(\epsilon|X, \delta > -X\pi - W\theta). \quad (7)$$

From Johnson and Kotz (1970 p. 81, 1972 p. 112),

$$E(\epsilon|X, \delta > -X\pi - W\theta) = \frac{\text{cov}(\epsilon, \delta)}{\sigma_\delta^2} E(\delta) \quad (8)$$

$$= \frac{\text{cov}(\epsilon, \delta)}{\sigma_\delta^2} \left(\frac{\sigma_\delta f(-X\pi - W\theta)}{1 - F(-X\pi - W\theta)} \right)$$

$$= \frac{\text{cov}(\epsilon, \delta)}{\sigma_\delta} \left(\frac{f(X\pi + W\theta)}{F(X\pi + W\theta)} \right).$$

Equation (8) results from the fact that $E(\epsilon)$ is affected by δ being truncated from below.

Since $\sigma_\delta > 0$, the critical quantity in (8) is the covariance between the structural error, μ , and the attrition probability error, δ . If $\text{cov}(\epsilon, \delta) \neq 0$, then the whole second term on the right side of (8) is non-zero. As noted by Heckman (1979), the general sample truncation problem can be equated with ordinary specification error arising from omitted variables in regression analysis. If $\text{cov}(\epsilon, \delta) = 0$, the term drops out from (6) and β is unbiased.

Let

$$\left(\frac{\text{cov}(\epsilon, \delta)}{\sigma_\delta} \right) = \lambda$$

and

$$\frac{f\left(\frac{X\pi + W\theta}{\sigma_\delta}\right)}{F\left(\frac{X\pi + W\theta}{\sigma_\delta}\right)} = Z. \quad (9)$$

Then, by adding an error term, equation (6) becomes

$$E(y|x, D=1) = X\beta + \lambda Z + \xi \quad (10)$$

Therefore, a convenient test for attrition bias is the significance of λ ; if it is significant, the omitted variable, Z , is an important explanatory variable and needs to be included to estimate β without bias.

Estimation

Several approaches have been developed to estimate the parameters of (10). The most complex approach is to use maximum likelihood methods (Hausman and Wise 1979, Griliches, Hall, and Hausman, 1977). However, Heckman (1976) proposed a relatively simple estimator that is useful for exploratory data evaluation.

At a given point in time (wave) in the panel, the steps of Heckman's procedure are:

1. Estimate equation (4) using probit analysis (Finney 1964) on the whole sample. That is, at that point in time, $D=1$ for a person still in the sample, $D=0$ for an attriter.
2. From the parameter estimates of step 1 ($\hat{\pi}$, $\hat{\theta}$, and $\hat{\sigma}_\delta$), estimate Z as shown in (9) for each member of the sample still left.
3. The estimate of Z , \hat{Z} , is then used in equation (10) to estimate λ and β by ordinary least squares (OLS). This procedure produces consistent estimates of $\hat{\beta}$ and $\hat{\lambda}$. However, if $\hat{\lambda} \neq 0$, σ_ϵ^2 from (10) is underestimated

as ξ is heteroscedastic (Heckman 1976, p. 480). This will produce inflated estimates of the significance of β and λ . Therefore, generalized least squares (GLS) rather than OLS can be used in step 3 of the estimation procedure (Heckman 1979). However, using OLS in step 3 makes the attrition bias correction factor straightforward to implement using commonly available computer routines.

Data

The data utilized in this study are from Farley, Howard, and Lehmann (1976). A panel was constructed from a national probability sample of respondents expressing some interest in purchasing subcompact cars within the subsequent two years. Four waves of telephone interviews were conducted over a fifteen-month period with people who would be principal drivers of the new subcompact car if purchased.

Because many questions were asked in each wave and there were eight brands in question, the panel was divided into four groups which were each questioned about only four of the eight brands. Information about the brand used in this study, the Chevrolet Vega, was requested by all four groups. Table 1 demonstrates the attrition rate for the four groups over the four waves.

TABLE 1

Group	Sample Sizes for the Groups of Respondents Over Time				Total Attrition Rate
	Wave				
	1	2	3	4	
1	305	229	213	192	37%
2	328	251	206	171	48%
3	288	219	197	169	41%
4	316	239	205	177	44%
Total	1237	938	821	709	43%

As can be seen, the attrition problem with this panel was substantial despite the fact that the panel was of ordinary design compared to other longitudinal data bases.

Models

Structural Model

The model employed is based on the Howard-Sheth model of buyer behavior (Howard and Sheth 1969) and is a variant of that utilized by Farley, Howard, and Lehmann (1976). It is a four-equation system explaining the endogenous variables Intention, Attitude, Confidence, and Brand Comprehension. The model has the form

$$By' + \Gamma x' = \mu \quad (11)$$

where

$$B = \begin{bmatrix} -1 & \beta_{f2} & \beta_{13} & 0 \\ 0 & -1 & 0 & \beta_{24} \\ 0 & 0 & -1 & \beta_{34} \\ 0 & 0 & 0 & -1 \end{bmatrix}$$

$$\Gamma = \begin{bmatrix} \gamma_{10} & \gamma_{11} & 0 & 0 & \gamma_{15} & \gamma_{16} & 0 & 0 & \gamma_{19} & 0 & 0 & \gamma_{112} \\ \gamma_{20} & 0 & \gamma_{22} & 0 & 0 & 0 & \gamma_{26} & \gamma_{27} & \gamma_{28} & \gamma_{29} & \gamma_{210} & 0 \\ \gamma_{30} & 0 & 0 & \gamma_{33} & 0 & \gamma_{35} & \gamma_{36} & \gamma_{37} & \gamma_{38} & 0 & \gamma_{310} & 0 \\ \gamma_{40} & 0 & 0 & 0 & \gamma_{44} & \gamma_{45} & \gamma_{46} & 0 & \gamma & 0 & \gamma_{410} & \gamma_{411} \end{bmatrix}$$

and the ij index refers to equation i and variable j . y is a 4-element vector of the endogenous variables, x is a 12-element vector of exogenous variables, and μ is a vector of disturbances. The variables can be found in Table 2.

TABLE 2

Variable List

Variable	Definition
<u>Endogenous</u>	
Intention (y_1)	Intention to purchase Vega during next three months, 1-10 scale
Attitude (y_2)	Overall liking of Vega, 1-10 scale.
Confidence (y_3)	Respondent's perceived ability to judge Vega 1-10 scale
Brand Comprehension (y_4)	The number of correct answers to a set of objective questions about Vega
<u>Exogenous</u>	
Intention ($t-1$) (x_1)	Lagged Intention
Attitude ($t-1$) (x_2)	Lagged attitude
Confidence ($t-1$) (x_3)	Lagged confidence
Comprehension ($t-1$) (x_4)	Lagged comprehension
Advertising Recall (x_5)	Summed recall of specific copy points for Vega
Propensity (x_6)	Intention to buy product class within 2 years, 1-10 scale
sex of respondent (x_7)	0=female, 1=male
age of respondent (x_8)	10 category ordinal scale
Income (x_9)	Reported, 10 category ordinal scale
Education (x_{10})	Number of years of schooling
Number of Drivers (x_{11})	In household
Child (x_{12})	If principal driver would be a child (1=yes, 0=no)

Attrition Model

As noted earlier, previous research has found that interest in the study tends to be related to the probability of a panel member dropping out. Interest in the study, when unmeasured, is likely to be a function of demographic/socioeconomic variables and other exogenous factors. Therefore, the attrition model is assumed to be composed of the reduced-form variables from the system described by equation (11). That is, by some matrix algebra, equation (11) can be represented by

$$y' = -B^{-1}\Gamma'x' + B^{-1}\mu \quad (12)$$

$$= \pi x' + v.$$

In addition, there is empirical evidence that the four groups comprising the panel differ with respect to means of endogenous variables some slopes of exogenous variables (Farley, Katz, Lehmann, and Winer 1980), and attrition rates (Table 1). To partially account for this, group dummy variables to reflect possible mean differences in attrition probabilities were added. The attrition model thus becomes

$$D = \sum_{i=0}^{12} \pi_i x_i + \sum_{i=1}^3 \alpha_i G_i + v. \quad (13)$$

where D is the 0-1 index of being in or out of the sample for a given wave, the independent variables are from Table 2, and the G_i are 0-1 dummies representing three of the four groups.

Empirical Results

Attrition Model

The results of the probit estimation of the attrition model (13) for waves 2, 3, and 4 are in Table 3. Since sex, age, income, education, number of drivers, and child are measured only once in the first wave, those variables must be repeated for each wave. However, intention through propensity (Table 3) are measured in each wave.

TABLE 3
Probit Results from Attrition

Variable	Wave 2	Wave 3	Wave 4
Constant	.7637**	.2055	.0332

sig. log. likelihood (15d.f.)	$p < .30$	$p < .20$	$p < .05$

* $p < .10$ ** $p < .05$ two-tail tests

Since panel dropouts obviously are not measured on these variables in the wave they attrite and on, a decision had to be made on the appropriate values to use. Therefore, for all panel members, the wave one values were employed. The only difference between the data matrices for the wave 2, 3, and 4 attrition models was thus in the 0-1 dependent variable.

As can be seen from Table 3, the reduced form variables are only weakly related to the probability of attrition for waves 2 and 3. However, by wave 4, more people had dropped out providing increased information on which to base the

relative effects of the exogenous variables. The results indicate that age is negatively related to staying on the panel and income has positive influences. These results are consistent with the findings in the literature reported earlier. A weaker effect was that people with higher confidence in their ability to judge the Vega tended to drop out. Perhaps, this reflects a feeling that there was little additional knowledge to be gained from being on the panel which translates to a low interest factor.

Structural Model

As described earlier, the probit results are used to create a new independent variable to be added as an explanatory variable to the equations (11). The implications of panel attrition can be found in Tables 4-6 by comparing the results with and without the attrition bias correction factor. OLS was used to estimate each equation as the model is assumed to be recursive with independent inter-equation errors. Tables 4-6 may be found in the appendix at the conclusion of this paper.

In this instance, attrition appears to have a modest impact on the structural equation estimates. The correction factor is significant in three cases--the Confidence equation in wave 2, the Confidence equation in wave 3, and the wave 4 Attitude equation. In all three cases, the impact of attrition is selective; not all variable coefficients are affected. In fact, the effects seem to be centered on the pure exogenous variables rather than the endogenous variables that are exogenous. In the Confidence-wave 3 equation, the greatest impact is on the age variable as it doubles in size and becomes significant. In the Attitude-wave 4 equation, the income variable assumes a much larger value and becomes significant. If the model was being used for segmentation purposes, serious misallocations of resources or missed opportunities could result.

Discussion

It is difficult to determine when attrition should be modeled as part of a structural system. Hausman and Wise (1979) provide empirical evidence supporting the notion that bias is more likely to be present when the structural model is misspecified. This implies that in early stages of model development or when simplicity is sought at the expense of completeness, attrition bias can seriously distort results. The model utilized in this paper has been thoroughly tested and found to be robust to minor perturbations in specification. Therefore, it is not surprising that correcting for attrition did not have a dramatic impact on the empirical results. Even with this relatively well-specified model, however, the impact of panel attrition can be seen.

Several other issues can be raised. First, if a wave-by-wave analysis is not desired but the analyst wishes to pool, only panel members completing all waves can be used. Therefore, the implication is that only one attrition model need be estimated--the one corresponding to the wave four analysis of Table 3--since interest is focused on predicting the probability of attrition by the final wave. Second, if attrition and missing data occur, both problems could be modeled and two terms inserted in each structural equation. There may be difficulty, however, in separately identifying missing data and attrition functions.

Conclusion

This paper has developed and estimated a model that accounts for attrition bias in panel data. It was found that the main impact of attrition was on exogenous variables and not endogenous variables that were exogenous in the equations. Marketing studies employing panels should be aware that attrition can affect model parameter estimates, particularly

if the model structure is not well-known.

SCIENTIFIC ADVANCEMENT IN CONSUMER RESEARCH: SOME PROBLEMS
ENCOUNTERED WHEN USING CONSUMER PANEL DATA¹

R. Dale Wilson, Batten, Barton, Durstine & Osborn, Inc.²

Abstract

Numerous studies have been conducted over the past twenty years which utilize diary panel data in testing particular components of consumer behavior theory. This paper addresses the use of such data and provides empirical illustrations of some of the important problems which may improperly alter the development of theoretical advances in consumer behavior.

Introduction

The widespread availability of diary panel data for use in consumer research has presented many opportunities for the creative researcher. During the past twenty years, studies in consumer research have used panel data to track consumer brand choice decisions, to investigate shopping behavior strategies, and to draw inferences about consumer response to marketing variables (such as short-term promotional programs and price differentials among national and private-label brands) among others.

Unfortunately, however, significant problems are likely to be encountered when diary panel data are used for these purposes. Some, primarily those dealing with traditional measurement error, are well documented. Other problems, however, are largely ignored in the consumer behavior literature. This latter class of difficulties include operational problems such as multiple purchases, time duration between purchases, quantity (i.e., size of package) purchased, and purchase of multiple brands at one purchase occasion.

While some researchers dismiss these problems casually, their influence on empirical findings (and thus consumer behavior theory) may be substantial. The purpose of this paper is to (1) address these problems, (2) document some of these problems with empirical data, and (3) suggest the limitations of panel data in consumer research from an advancement of science perspective. As such, the conflict between requiring near-perfect data for empirical work and accepting "less-than-perfect" panel data for testing theoretical constructs is illustrated.

Perspectives from Philosophy of Science

There seem to be several concepts from philosophy of science which may be useful in understanding the problems associated with many studies using consumer diary panel data. This section of the paper provides a brief discussion of these concepts--first as they relate to construct measurement in general and then as they relate to construct measurement when using panel data.

Empirical Indicators and Their Validity

The importance of measurement in consumer behavior research cannot be denied. Yet, at the same time, many consumer behavior studies are conducted without proper

attention to validation of the construct being measured. Dubin (1978, p. 182) uses the term "empirical indicator" to label the act of deciding the type of operation a researcher employs to secure a measurement of value on the unit under investigation. Empirical indicators simply serve as an observable representation of the theoretical construct of interest. The question remains, however, whether a particular empirical indicator is a valid representation of the theoretical construct.

Dubin (1978) addresses the issue of validity by pointing out that the term "validity" refers only to the consensus or lack thereof that a particular empirical indicator measures values on a stated unit. He continues by stating that:

"This consensus is a man-made consensus and is nothing more than a conventional agreement among a group of interested students and spectators that the empirical indicator and theoretical unit whose values it measures are homologous. We may therefore expect that what is a valid measure at some time may lose this status if the consensus upon which it is based is supplanted."

"The breakdown of a consensus usually occurs when an investigator raises questions about the empirical indicator based upon evidence that is independent of the circumstances of its employment" (p. 200).

Since construct validation is concerned with (1) what the measurement of a variable is in fact measuring and, more importantly, (2) the deductions that are being made about the theory underlying the measured variable (Churchill 1979 p. 258-9; Green and Tull 1978, p. 198-9), Dubin's emphasis on a "consensus" approach to measurement cannot be slighted. Another point worth mentioning is that the potentially large degree of measurement error in the behavioral sciences causes the issue of the validity of empirical indicators to be especially important. In the natural sciences, where there is a much closer correspondence between reality and appearance, validity is of little concern (Dubin 1978, p. 202).

Since the study of consumer behavior is a social science, the importance of measurement in our discipline cannot be denied. Yet, in many cases, we behave as if measurement issues are beyond the realm of concern. For example, Jacoby and Chestnut (1978) identify a total of fifty-three separate measures of "brand loyalty." Many of these measures, when evaluated critically, probably have little relationship to the theoretical construct of brand loyalty. Other examples from the consumer behavior literature are also available which point to the real lack of concern for construct validity. Likely candidates include many attempts to measure such variables as deal proneness, advertising effectiveness, innovative behavior, perceived risk, information processing, values, personality, brand or store preference, etc. The point here is not to criticize those researchers who have attempted to measure illusive constructs. Rather, it is to draw attention to the special problems of construct validity when measuring variables that fall outside the realm of what might be termed

"absolute indicators."³

One insightful way to view the problems encountered when measurements are taken on a theoretical construct is to view the measured response as the sum of the true response plus possible measurement errors (see Lehmann 1979, p.106). Even more exasperating is the realization that when a statistical analysis is performed on the measured concept, the sources of potential error are many. This problem can be viewed as:

$$\text{Statistical test of a measured concept} = \text{True value} \\ + \text{Construct validation error} + \text{Measurement error} \\ + \text{Statistical error}$$

where:

"True value" represents the actual, yet unobservable, response which one is attempting to measure;

"Construct validation error" represents the unobservable difference between the true value of the response and the measurement of that response (disregarding measurement error);

"Measurement error" represents such partially unobservable factors as measurement process error, instrumentation error, and respondent error (see Lehmann 1979, p. 103-6); and

"Statistical error" represents error in the definition and selection of the sample as well as the error in the execution of the sampling plan. Statistical error also tends to be unobservable.

While many researchers have actively sought methods for limiting or controlling measurement error and statistical error, far less attention has been given to the problem of construct validation error in consumer behavior.

Construct Measurement Via Panel Data

For the purpose of this paper, discussion is limited only to measurement issues in continuous, diary panels which allow respondents to use self-administered questionnaires to record prespecified information on a regular basis (see Tull and Hawkins 1976, p. 397-401 for a concise analysis of the various types of panels, their characteristics, and their uses). Sudman and Ferber (1979), in the most comprehensive description of consumer panels and resulting data that is available in the literature, provide an analysis of the types of consumer and market research studies conducted with panel data.

It is important to note that discussions of consumer diary panels by and large ignore measurement problems associated with construct validity. Sudman and Ferber (1979) discuss measurement problems in consumer panels as including only sample representativeness, data accuracy, and panel conditioning. Similarly, others, such as Morrison, Frank, and Massy (1966) and Buck et al. (1977) mention the limitations of panel approaches to data collection but do not delve deeper into construct validity questions. Powers, Goudy, and Keith (1978), in addition to discussing the traditional limitations, compared panel data with recall data and found

³"Absolute indicators" are those that are ". . . absolute in the sense that there can be no question as to what they measure" (Dubin 1978, p. 193). Examples, according to Dubin, include all demographic characteristics. One may argue, however, that because measurement error can never be totally eliminated, the definition of absolute indicators should include some relative notion of the degree to which there can be no question as to what they measure.

major inconsistencies. In an article which discusses methods that may ultimately be useful in shedding light on validity issues, McCullough (1978) reviews four methods which are appropriate for determining causal effects in panel data studies. These methods include Lazarfeld's 16-fold table, Coleman's four-state continuous-time Markov processes, cross-legged panel correlation, and path analysis.

Thus, the literature indicates that for the most part, there is little concern for construct measurement. But as indicated by McCullough's (1978) review, it may be possible to design studies to determine cause and effect relationships and clarify measurement issues by testing alternative definitions of constructs where the causal relationships are clear. If such cause and effect relationships are thought to be known with a high degree of certainty, then several definitions of a construct could be substituted for the purpose of selecting the best definition.

Although it is not entirely clear from reading the literature on the collection and analysis of panel data, the major factor which adversely affects construct validity is the fact that researchers rarely have the opportunity to measure constructs in the way in which they desire. Thus, with rare exception in the published literature, secondary data is being used. Another factor, nearly as important as lack of control in data collection, is the tendency toward using self-reported behavioral data to attempt to measure variables that may consist either fully or partially of attitudinal or cognitive components. Jacoby and Chestnut's (1978) criticism of much of the existing brand loyalty literature is a case in point. These two problems, one associated with the inability to obtain empirical indicators in exactly the way one wishes and the other associated with the necessity of using strictly behavioral data to measure attitudinally- or cognitively-oriented constructs, causes users of consumer panel data to be less than perfect in their data requirements. Unfortunately, however, these problems probably have had an adverse effect on the growth and development of consumer behavior theory.

Empirical Illustrations

The question, "Are we really measuring what we think we're measuring?", may never be answered with any degree of certainty for many constructs. However, it may be instructive to point out how the quality of measurement is affected by what may be "oversimplistic" empirical indicators. It is hoped that the few empirical illustrations included here will stimulate more critical thinking on the hazards of using panel data in cases where the quality of the empirical indicator is in doubt.

Illustration I--Measuring Brand Purchase and the Problem of Multiple Units

A priori, one would expect that the measurement of actual brand choice would present no problem to the research given the ease with which purchase behavior could be pulled from the diary records. Unfortunately, such simplicity does not exist due to the problem of multiple purchases at a single point in time. Because of convenience, the availability of deals, or for other reasons, many consumers often buy multiple units (or even multiple brands) on a given shopping trip. For example, Wilson, Newman, and Hastak (1979) present panel data collected over a 24-month period which indicates that for the bar soap category, 68.5% of all purchases consisted of two or more units. In addition, 31.8% of the purchases consisted of three or more units and 22.5% consisted of four or more units. The most regrettable aspect of this situation is that most researchers have not revealed their methods for handling multiple-unit purchases. The available literature implies that this problem is usually handled in one of two ways--either through the truncation of all units purchased after the first (or a randomly-selected one) or the consideration of each unit

as independent purchase occasions (Wilson, Newman, and Hastak 1979). Regardless of the option chosen by a particular researcher, it is clear that the difference between the true value of brand purchase and the measured value may be great.

Illustration II--Measuring Deal Purchases

Although the trend toward purchasing in multiple quantities is interesting, there may be more to the data than is originally apparent. It stands to reason that one may be interested in determining why such behavior took place and, therefore, would want to determine how many purchases occurred in conjunction with dealing activity. In these cases, data on multiple units purchased would also contribute to an understanding of the effects of a particular type of deal. Again, however, the number of units purchased is rarely (if ever) considered in studies of consumer dealing activity even though it provides a possible explanation for the true impact of such deals.

Table 1

Type of Deal Situation	Number of Units Purchased Per Occasion					
	1	2	3	4	5 or more	Total
No Deal	10,535 (39.9%) ^a	9,315 (35.3%)	1,822 (6.9%)	3,692 (14.0%)	1,032 (3.9%)	26,396
Media-Distributed Coupons	341 (14.4%)	1,184 (50.0%)	415 (17.5%)	339 (14.3%)	90 (3.8%)	2,369
Package Coupons	254 (17.8%)	780 (54.6%)	203 (14.2%)	156 (10.9%)	35 (2.5%)	1,428
Cents-Off Marked	1,107 (14.9%)	2,702 (36.4%)	946 (12.7%)	1,656 (22.3%)	1,022 (13.7%)	7,433
Multiple Deals and Other Types	214 (9.3%)	705 (30.8%)	341 (14.9%)	798 (34.9%)	231 (10.1%)	2,289
Total	12,451 (31.2%)	14,686 (36.8%)	3,727 (9.3%)	6,641 (16.6%)	2,410 (6.0%)	39,915

Chi square with No Deal condition included = 4,527.14 with degrees of freedom, significant at $p < .0001$.

Chi square with No Deal condition excluded = 883.25 with 12 degrees of freedom, significant at $p < .0001$.

^aThe numbers in parentheses are row percentages.

Table 1 is designed to help clarify how the type of deal relates to multiple purchases. As can be seen from the table, the row percentages point to several differences in the number of units purchased across the various types of deals. Further, these trends tend to be accentuated as the number of units purchased increases. For example, four units are purchased in 22.3% of the cents-off marked coupon deals but in only 10.9% of the package coupons. The large chi-square statistic indicates that a strong relationship exists between the deal type and the number of units purchased. Thus, if a consumer researcher attempted to measure the impact of various types of deal situations without considering the purchase of multiple

units, major errors could be made due to the oversimplification of the purchase measure.

Illustration III--Types of Deals Purchased Over Time

One of the problems often associated with studies involving consumer panels is that interesting trends in the data are camouflaged by the level of aggregation of that data. Because of the high costs of processing panel data, researchers sometimes tend to draw conclusions about trends in the data without a detailed analysis. In working with panel data, it is abundantly clear that "how you cut the data" will have a large influence on conclusions that are drawn. In a philosophy of science sense, this problem is especially important whenever cause and effect relationships are being specified.

As an illustration of this problem, first consider the data in Table 2. This table presents data in the bar soap category for the total market in 1976 and 1977. Specific data are also presented for five brands, each having a relatively large market share among panel respondents over the two-year period. Table 2 points out clearly the temporal effects of sales. At first glance, the total market for the category seems to be declining over time since total units purchased declined from 4,976 to 2,959. Further,

Table 2

TOTAL UNITS PURCHASED BY BRAND							
Yr.	Qtr.	Total Units Purchased					
		All Brands	Brand A	Brand B	Brand C	Brand D	Brand E
1976	I	4,095 (10.2%) ^a	751 (18.3%)	442 (11.6%)	361 (10.2%)	235 (8.1%)	44 (1.4%)
	II	4,976 (12.3%)	974 (23.8%)	494 (13.0%)	451 (12.8%)	335 (11.6%)	59 (1.9%)
	III	5,805 (14.4%)	938 (22.9%)	612 (16.1%)	488 (13.8%)	445 (15.4%)	71 (2.2%)
	IV	6,990 (17.3%)	823 (20.1%)	620 (16.3%)	658 (18.7%)	448 (16.9%)	258 (8.1%)
1977	I	5,836 (14.5%)	262 (6.4%)	543 (14.3%)	556 (15.8%)	417 (14.5%)	834 (26.3%)
	II	5,009 (12.4%)	149 (3.6%)	424 (11.1%)	416 (11.8%)	360 (12.5%)	790 (24.9%)
	III	4,627 (11.5%)	126 (3.1%)	412 (10.8%)	353 (10.0%)	367 (12.7%)	673 (21.2%)
	IV	2,959 (7.37%)	75 (1.8%)	262 (6.9%)	245 (6.9%)	237 (8.2%)	444 (14.0%)
Totals	40,297	4,098	3,809	3,528	2,884	3,173	
Total units purchased at regular price	26,396	1,967	2,817	2,470	2,300	1,554	
Percentage of units purchased at regular price	66.1	48.0	74.0	70.0	79.8	49.0	

^aThe numbers in parentheses are column percentages.

this trend is not explained when specific brand data (at least for Brands A through E) are analyzed. One interesting feature of the inter-brand relationship is that the units purchased figures for Brand E show dramatic increases in time. Like all of the brands displayed in Table 2, however, Brand E sales seem to be declining quickly after a peak of 834 units in the first quarter of 1977.

The key to understanding the bar soap data, however, may be in the last two rows of Table 3, which represent the total number of units and the percentage of units purchased at regular price. Across all brands, 13,901 (or 34.5%) of the 40,297 units purchased were bought on deal. For some brands, such as Brands A and E, over 50% of the total units were purchased at a deal price. Thus, the simple inclusion of dealing activity may inspire us to look further into the data for explanations of the cause-effect relationships.

Table 3, 4, and 5 present the purchase data for Brands A, B, and C, respectively. These tables are designed to more clearly establish the relationship between dealing activity and units purchased across time. Except for the Brand A

Total for 1976 and 1977		985	918	1,024	882	3,809

Chi square for 1976 data = 61.04 with 12 degrees of freedom; significant at $p < .0001$.

Chi square for 1977 data = 53.84 with 12 degrees of freedom; significant at $p < .0001$.

Chi square for combined 1976 and 1977 data = 126.25 with 28 degrees of freedom; significant at $p < .0001$.

data in 1977, the chi-square statistics presented in the tables indicate that the hypothesis of independence between dealing activity and time period must be rejected. Since there does seem to be an identifiable relationship here, it seems appropriate to suggest further study of the cause and effect relationships between units purchased and dealing activity. Particularly for Brand A, it appears that the lack of deal availability during calendar year 1977 may have caused, or at least accentuated, the decline in units purchased among panel members.

Illustration IV--Measuring Store Choice

Table 6 presents shopping and purchase expenditure data for a panel of 719 respondents who resided in the Chicago area. These data were collected over a four-week period in 1970 by a national consumer panel organization. The interest in these data lie in the fact that the determination of market share is quite difficult. For Store A, a large regional supermarket chain based in Chicago, the data indicate a monotonically increasing relationship between the dollar amount category and the percentage of trips made to Store A. If one considers "market share" to be equal to the number of shopping trips made to Store A divided by the total number of trips made to all stores, then the ques-

Table 5

PURCHASES BY TYPE OF DEAL AND TIME PERIOD

Total for 1977		556	416	353	245	1,570
Total for 1976 and 1977		917	867	841	903	3,528
Chi square for 1976 data = 65.34 with 12 degrees of freedom; significant at $p < .0001$.						
Chi square for 1977 data = 133.60 with 12 degrees of freedom; significant at $p < .0001$.						
Chi square for combined 1976 and 1977 data = 214.52 with 28 degrees of freedom; significant at $p < .0001$.						

tion becomes, "What is the relevant measure of store shopping trips?"

The data in Table 6 indicate that when all purchases are considered, Store A's market share is 25.2%. However, a more suitable measure of Store A's actual impact on the marketplace may be obtained by considering only those trips in which a particular minimum amount was spent. For example, if the relevant cutoff is at an expenditure level of \$5.00 the market share figure increases to 33.9%.

The point of this illustration is that a great deal of thinking must be done in order to establish the point at which minor, "filler" shopping trips become larger, "full-scale" trips. Using the data presented in Table 6 as justification, Wilson (1977) used the \$5.00 point as the relevant cutoff point. Similarly, Frisbie (1980) chose the \$5.00 point as one of his three criteria for establishing filler trips. In these cases, there are no firm theoretical reasons for defining filler trips in a particular way although the concept does have some support in the literature (e.g., MacKay 1973). However, as Table 6 illustrates, this problem is meaningful if a clear picture of consumer shopping behavior is to emerge from the panel data.

Discussion

One of the main points that, hopefully, will come from this paper is that because of measurement problems, the analysis of consumer panel data is no simple task. Although this point has been illustrated with only one example (i.e., the problem of multiple purchases), many other far more difficult definitional problems come to mind. For example, the early work of Kuehn and Rohloff (1967) indicates consumers surprisingly maintain a high degree of "size loyalty" and, in fact, their findings include evidence that loyalty to package size is occasionally more typical than brand loyalty. Yet, it is not surprising that researchers have avoided using panel data to explore size loyalty since variations in within-brand and across-brand package sizes would be virtually impossible to control. Not only would one have to consider the package size, but other factors such as the specific brand, deal availability, number of units purchased, and perhaps consumers' usage rate would become relevant to the analysis. Control procedures for such a study would have to be massive.

Another point to be made is that variable measurement is of utmost importance. However, the use of convergent validity, which requires the measurement of multiple dependent variables in panel studies, should be useful in limiting the extent of this problem (see Dubin 1978, p. 195-200; Jacoby 1978).

Lastly, another problem of no small significance is the fact that the huge quantities of data available on the typical magnetic tape of panel records sometimes hides relevant data. Wiggins (1973) addresses this problem when he discusses one of the three main uses of panel data--to study change on the behavior of individuals, as in studies of buying behavior. He states that:

"[this type of application]...has great significance in its own right, and its own variety of unique problems. A tremendous amount of potentially valuable findings may have been ignored by trying to eliminate what for the purpose at hand was garbage (or merely irrelevant to the problem), even though a detailed examination ...may have yielded other kinds of information of genuine value....The problem there has generally been a shortage of funds and possibly a lack of sophistication in the analysis in some instances" (p. 188).

Also related to problem discussed by Wiggins is the fact that extremely large sample sizes in most panels (see Sudman and Ferber (1979, p. 9-11) may mislead the researcher by causing immaterial deviations to be statistically significant. More care needs to be taken to avoid the problem of "failing to see the forest for the trees."

Conclusion

This paper has attempted to point out a few of the many pitfalls of using diary panel data in consumer research. More than anything else, the paper was designed to provide cautionary comments to current and future data users. While it is clear that the availability of panel data presents many opportunities for meaningful, creative research, panel data can also lead to unthinking data massaging that yields non-productive or even counter-productive conclusions. The goal of advancing the discipline of consumer research dictates that panel researchers engage in more than rote number crunching with high-powered hardware.

Table 6
SHOPPING AND PURCHASE EXPENDITURE DATA^a

Dollar Amount Category	Number of Trips	Mean Dollars Spent Per Trip	Standard Deviation	Number of Trips to Store A	Percentage of Trips to Store A
All Purchases	10,767	8.80	11.42	2,715	25.2%
All Purchases ≥ 1.00	9,419	9.97	11.76	2,548	27.1%
All Purchases ≥ 2.00	7,716	11.87	12.22	2,270	29.4%

DECOMPOSING THE CORRELATION MATRIX IN PANEL DATA

Donald R. Lehmann, Columbia University
John U. Farley, Columbia University

Abstract

ANOVA is suggested as an approach to decomposition of a correlation matrix as an aid to model building. The decomposition proceeds sequentially from a simple "direct effects" to a "significant effects" model relating four constructs measured in two waves of a panel study tracking the introduction of a new small automobile.

The correlation matrix serves as the basis for many types of analysis, including two-variable association, multiple-relationship structural models and reliability and validity studies. Methods of analysis include coefficient alpha, multi-trait and multi-method approaches to the analysis of within-construct and among-construct correlations, factor analysis for assessment of variable structure and dimensionality, and regression and path analysis for estimation of structural parameters linking different constructs. When multi-wave and/or multi-brand data are available, the correlation matrix has regularities that may offer special information useful for systematic model building. This paper describes a direct approach to analysis of patterns in a correlation matrix. The approach is designed to help gain insight into structure in a set of variables in situations when repeat measurement is available.

The Approach

The basic approach involves decomposing the set of zero-order correlations with analysis of variance, attempting to explain the correlations on the basis of combinations of variable, construct and remeasurement patterns. The approach, which has similar goals as approaches for deducing structural relationships among a set of variables (Baggozi 1979, Joreskog and Sorbom 1977), can be summarized as follows:

1. Underlying constructs are assumed to be linked causally.
2. Constructs are assumed to be measured with error.
3. Errors are assumed to have a correlated error structure.
4. Multiple measures are available on constructs over time, over multiple items or both.
5. An ANOVA incorporating direct effects (e.g., wave, brand, construct or variable) is used to assess "base-level" correlation in the data which may represent response style (Gruber 1979) or some other "common factor" characteristic of the measurements.
6. Interactions (combinations of waves, constructs and variables) are specified to model particularly strong or weak relations among variables and hence to suggest intertemporal or intervariable links for a causal model.

This ANOVA approach is similar in spirit to the log-linear method for analysis of individual traits, in that it sequentially tests various effects to assess the impact of that particular variable on patterns of intercorrelations.

Different types of data configuration make different types of ANOVA models appropriate. Some possibilities are shown for illustration in a two-wave correlation matrix in Figure 1.

a) for any single-wave study, a triangular correlation matrix such as I is available. In this case, it is possible

to develop a model including both multiple measurements within construct and relationships between constructs.

b) for a two-wave study using different respondents, two such triangles (I and II) are available. Insofar as measurement is on parallel constructs (e.g., $K = M$ and each set of measurements is identical) a parallel model can be estimated viewing the two triangles as replications. A similar approach can be used for two stimuli measured identically on either the same or different samples. Both will yield two triangular correlation matrices which can be viewed as replications.

c) remeasurement on the same respondents either over stimuli in a cross section or over time as in a panel (or both) produces a series of rectangular correlation matrices like III, in addition to triangles I and II. When identical measurements are used on each wave or stimulus, III is square and test-retest reliabilities of the measurements appear on the main diagonal.

Direct decomposition of the correlation matrix uses various features of construct, repeated within-construct measurement, time and stimuli to develop design patterns to be used in analysis of variance models for assessing patterns of systematic differences in arrays of correlations of the type shown in Figure 1. The design matrix for the ANOVA will be ideosyncratic to a particular application, depending on the number of waves, the extent to which parallel measurements are used, and the extent to which measurements on different stimuli (usually brands) can reasonably be viewed as replications. Further, the number of available square cross-wave and cross-stimuli matrices determines the number of replications or semi-replications available, which in turn determines the extent to which various second- and higher-order interactions can be incorporated into the ANOVA design.

An Application

The approach is illustrated in an analysis of four single-measure constructs which constitute the core endogenous variables in a consumer choice model (Farley, Howard and Lehmann 1976):

Intention to buy brand i
Attitude toward brand i
Confidence in ability to judge brand i
Perceived knowledge of brand i

There is theoretical reason to expect systematic contemporaneous inter-construct relationships, and there may be important inter-temporal relationships as well. The data consist of measurements on two waves of a national panel on small cars, with one wave taken immediately following the introduction of Vega and the other three months later. All constructs were measured by self-report on a 10 point bi-polar adjective scale. The analyses uses the correlation matrices for Volkswagen (an existing brand) and Vega (the new brand) shown in Table 1.

FIGURE 1
 Illustrative Two-Wave Multi-Construct
 Multi-Measure Correlation Matrix

The "full decomposition" ANOVA model is of the form:

$$r_{ijklmnpqs} = \mu + \alpha_i + \beta_j + \gamma_k + \delta_l + \phi_m + \xi_{nn} + \psi_{pq} + \epsilon_{ijklmnpqs} \quad (1)$$

- i = 1,2 brand
- j,k = 1,2 wave of row and column position in Table 1 respectively
- l,m = 1,2,3,4 variables in row and column in Table 1 respectively
- nn = 1-1,2-2,3-3,4-4 indicating remeasurement on the same variable
- p,q = 1,2,3,4 (p≠q) interaction terms pairings of different variables
- s = 1, ..., 56 the observation

TABLE 1
 Simple Inter-Variable Correlations for Volkswagen
 (Above Major Diagonal) and Vega (Below Major Diagonal)

VOLKSWAGEN									
Construct	WAVE A				WAVE B				
	Intention	Attitude	Confidence	Knowledge	Intention	Attitude	Confidence	Knowledge

G Confidence	.133	.279	.398	.293	.220	.431	*	.267	
A Knowledge	.060	.185	.227	.495	.002	.154	.267	*	

Regression procedures were used for estimation. The design variables are binary and were coded +1, -1 so coefficients of a given effect sum to zero. Pair-wise interaction terms are formed by direct multiplication of the three direct effects (brand, wave and variable). The two brands are viewed as replications of the same data-generating process. Two different specifications of ψ_{pq} are used—one symmetric (e.g., $\psi_{pq} = \psi_{qp}$) and one in which the coefficients are not constrained to be equal.

Results

The results of the decomposition are discussed in terms of:

1. an assessment of residuals from a baseline "direct effects" model which leads to further inferences about model structure in the context of this potentially incomplete model. This model excludes ξ and ψ from (1).
2. tests on direct effects and pair-wise interactions in the full version of (1).
3. interpreting the parameters of an ANOVA model containing effects identified as significant in steps (1) and (2).

The Use of Residuals. A "direct efforts" model provides the baseline for assessment of possible interactions. Residuals from this ANOVA model, often disregarded in analysis of variance, provides guidance for improved specification. Patterns in the signs of the residuals from this parsimonious direct effects only model (Table 2) show clear underprediction of reliabilities and over-

prediction of cross-wave combinations of non-paired variables. The direct effects model does a reasonably good job predicting correlations of contemporaneous pairings. Further, it appears that a relatively small number of large underpredictions (particularly involving the reliabilities) offsets a larger number of smaller overpredictions (Table 3) in the cross-wave combinations.

These patterns motivate the use of a model incorporating interactions combining various pairings of variables measured across waves. The residuals thus provide guidance in structuring tests for specific interactions—a step necessary because the data base lacks the degrees of freedom for a full set of factorial interactions of all orders.

ANOVA Results. Conventional analysis of variance for the full model containing both direct effects and pair-wise interactions are shown in Table 4. Since the design is not orthogonal because of the configuration of the correlation matrices, only the partial sum of squares are attributed to the individual effects. Common variance components are omitted from the numerators of all F statistics. The results:

- 1) no significant difference was found over time in the correlations, even though the Vega was newly-introduced. It appears that intervariable structure becomes stable quite quickly, probably in part because the product class is well-known and heavily advertised.

TABLE 2
Residuals From Direct Linear Effect
Model Including Wave, Car and Variable

Brand	Vega				Volkswagen			
Variable- Combination	Cross-Variable Combination Residuals							
	Wave 1	Wave 2	Wave 1- Wave 2	Wave 2- Wave 1	Wave 1	Wave 2	Wave 1- Wave 2	Wave 2- Wave 1
Intention-Attitude	-.043	.093	-.056	-.063	.052	.041	-.024	.079

	Residuals for Reliabilities							
	Vega				Volkswagen			
Intention	.122				.257			
Attitude	.032				.338			
Confidence	.035				.098			
Knowledge	.322				.275			

TABLE 3
Sign Patterns of Residuals From
Direct Effects Model

	Residual sign positive (regression underpredicts)	Residual sign negative (regression overpredicts)	Number of correlations
Reliabilities (variable paired with itself over time)	8	0	8
Different variables paired in same wave	14	10	24
Different variables paired in different wave	1	23	24
	<u>23</u>	<u>33</u>	<u>56</u>

2) no significant difference was found between Vega and Volkswagen correlations despite significant shifts in means of three of these variables for Vega over the introductory period and absence of such shifts for Volkswagen (Farley, Katz, Lehmann and Winer, 1979). Stable inter-variable relationships can thus exist among key constructs describing consumer behavior even when the means of those constructs are shifting over time.

3) significant differences occur in correlations involving different individual variables. This indicates that the variables are not simply one "common factor" but measure different constructs.

4) a significant test-retest effect was found, indicating reliability and/or the existence of significant carry-over effect for individual variables.

5) an interaction effect also exists for individual variable pairs, indicating the presence of some type of model linking these variables. A test for symmetry of interactions (e.g., that the correlations of attitude and knowledge are different for different wave pairings) shows that the interactions are not asymmetric. This implies that the interactions are stable over time.

The Regression Coefficients. Additional insights into the nature of the data structure is provided by the regression coefficients from an ANOVA because the analysis of the sums of squares indicates existence but not direction of an effect. A reduced model consisting only of those variables identified by the ANOVA just discussed is used--the equivalent of pooling the sums of squares of the insignificant effects in Table 4 with those of the residual error term. The resulting "significant effects" model contains direct effects of variables, plus reliability and symmetric interaction terms. The coefficients (Table 5) are expressed in units of increment or decrements of correlation around the constant term which represents the grand mean. Among the individual variables, knowledge and attitude have incrementally positive effects while intention is incrementally negative and significant. The reliabilities add significant increments of correlation, while the interactions have modest negative effects.

TABLE 4
Results of ANOVA on Correlations

Source of Variation	Degrees of Freedom	Sum of Squares	F ratio

constant .242

Reports of ANOVA results often omit measures of goodness of fit which can be useful both for comparing alternative models for a given body of data and for comparing results from different but related studies (Farley, Lehmann and Ryan 1979) in terms of the ability of a model to grasp essential characteristics of a data generating process. The explanatory power of the "significant effects" model compares favorably with those of many semi-aggregate cross sectional models (Farley and Howard 1977), and with those containing various combinations of direct effects and interactions (Table 6) in this specific case.

TABLE 6
Coefficients of Determination
for Alternative ANOVA Models
Coefficients of
Determination

	Adjusted	Unadjusted
ANOVA model with direct effects only	.341	.449
ANOVA model with direct effects and reliabilities	.782	.830
ANOVA model containing only significant effects	.804	.848
ANOVA model with direct effects, reliabilities and constrained interactions	.816	.866
ANOVA model with direct effects, reliabilities, and unconstrained interactions	.804	.868

Discussion

This paper describes an ANOVA approach to direct decomposition of a correlation matrix on the basis of various

direct effects and specified interactions. The analysis can be developed sequentially from a parsimonious "direct effects" specification and can lead to a "significant effects" model involving direct effects and interactions. The approach can be used to:

- 1) identify factors causing systematic variation in the correlations;
- 2) identify patterns in appropriately classified residuals from an ANOVA for extension of the decomposition process;
- 3) describe the process generating the correlations using the coefficients of individual variables and the coefficient of determination for an ANOVA.

The approach can be especially useful for constructing a design for analysis of panel measurements when a theory that is essentially contemporaneous is being used. The ANOVA models are likely to be parsimonious and can provide integrated information on reliability of individual measurements over time, on within-construct validity and on general patterns in among-construct relationships. While such a correlation decomposition is not an end in its own right, it may be useful for integrating inter-temporal features of panel data into a general contemporaneous specifications of a structural model (Farley, Katz, Lehmann and Winer 1979).

RESEARCH PANELS IN CONSUMER BEHAVIOR

Robert Ferber, University of Illinois
Linda B. Lannom, University of Illinois

Introduction

Most panel or longitudinal studies are undertaken to study some aspect of consumer behavior, such as purchase patterns over time or people's experiences moving into and out of the labor market. Such uses of panels are becoming more commonplace, and deservedly so, because they provide information about consumer behavior that only can be obtained by the panel technique.

At the same time, the growing popularity of the panel technique has led to a few attempts to set up panels to study the technique itself. This type of panel is much less glamorous, since no substantive question or policy issue is under investigation, and hence there is no expectation of dramatic results that, say, 46% of milk drinkers have seen the light and switched to scotch. The fact remains, however, that research panels serve a vital function in investigating the reliability of this technique and showing how the efficiency of these panel operations can be improved. Accordingly, the purpose of this paper is to discuss the objectives and the functions of research panels and to indicate the types of uses to which they can be put. In addition, we shall present some results obtained with one type of research panel that has been operated by the Survey Research Laboratory for more than ten years.

Objectives of a Research Panel

Before discussing the objectives of this type of panel, it might be a good idea to explain what we mean by a research panel. First, we should make clear that by a panel or longitudinal study we are referring to a series of reinterviews of the same sample on the same subject. We classify a study as a panel only if at least two reinterviews are involved, since the one-reinterview case is more likely to be an experiment than a panel study. The reinterviews are usually made at regular intervals, and the same people and the same basic information are sought in each interview, though this does not preclude asking for additional information as well.

By a research panel we mean one where the primary focus is on some methodological aspect of a panel operation. This may include a panel that is to be used solely for experimentation with panel techniques or to investigate the cost or the feasibility of a large-scale panel by means of a pilot study. Research panels that we know of are invariably of the latter type. They may have objectives such as:

- a. To ascertain the types of problems likely to be encountered in that type of panel operation.
- b. To explore means of dealing with these problems.
- c. To obtain operating experience with such a panel over a period of time, especially, information on panel mortality, sampling biases over time, conditioning effects, and reactions to sensitive information.

Even though the focus may be on methodology, a research panel has to have a substantive focus as well. This is necessary to make the panel members happy, as well as the funding agency. Thus, it is hardly feasible to inform a sample of households that we plan to study how their answers or behavior may change over time as a result of membership in a panel. It is a lot easier, and more feasible, to tell them that we want to study how their saving and spending patterns change over time as their little monsters grow up and take over the household.

Moreover, this provides the opportunity to obtain useful information at the same time as valuable data are obtained on the more important methodological aspects. Also, it is easier for a funding agency to justify a methodological study when substantive results are to be obtained as well--policy makers do not easily comprehend spending tens of thousands of dollars to improve methodology with which they have little contact, whereas they are much more quick to see the value of a study that will give them more information on the feeding and control of the two-legged little monsters whom they run into all the time.

Some Experimental Considerations

The planning of a research panel involves all of the usual considerations of a sample survey plus a few additional wrinkles. Thus, we still have to consider what population will be studied, how to select a proper sample in light of the given objectives, how to design the questionnaire, how to deal with possible response and nonresponse biases, and so on. In addition, however, some factors have to be kept in mind that do not usually arise in the ordinary pilot, or experimental, study.

For one thing, any experimentation should not be destructive in the sense of losing an appreciable part of the sample, at least not till the end of the study. For example, in a long-term panel operation, one cannot start out by asking, say, half of the sample for a complete listing of their assets and debts on the very first interview, to measure the effect of asking for highly sensitive information. While the results of such a procedure would certainly provide a good measure of the effects of asking for highly sensitive information at the beginning, this procedure will also very likely lead to the loss of an appreciable part of the sample, so that the sample size available for later observation and experimentation will be sharply reduced.

For these reasons, any experiments built into a research panel have to be planned keeping in mind their effect on the amount of information to be collected and the type of experiments to be carried out at a later time. One other consideration is that any methods used with the panel to improve response have to be planned in terms of their possible effect on the conditioning of the panel members and the types of information that will be sought in the future. Thus, any incentives or premiums have to be selected very carefully. For example, if the focus of a panel study is on the financial behavior of households, one can hardly give as an incentive a book on how to save and invest money. While it would be nice for some purposes to obtain an exact measurement of the bias due to this type of incentive, it is much the wiser approach from the point of view of study design to simply assume there will be some appreciable effect and to focus on other types of incentives for the purposes of the study. To be sure, there is no reason why some experimentation with incentives, or with other variables, cannot be built into a research panel, but it becomes virtually crucial that each of the experimental treatments be independent of the attitudes or behaviors to be studied as part of the substantive purpose of the study.

A third consideration is that if the research panel is to be operated over a number of years, every effort has to be made to maintain rapport with the panel members and to keep in contact with them. This means that the interviews should not be so long as to irritate the panel members to

the point of dropping out, that procedures have to be developed for keeping in contact with the panel members and finding out if they moved, and that where possible, other measures be used to maintain their interest, such as periodic reports or even a newsletter. Incentives can also be very effective.

Of course, ideally a research panel, like any survey study, should be based on a carefully thought-out set of objectives accompanied by a detailed set of data collection plans and analytical methods for meeting these objectives. In practice, this is hardly feasible with a research panel, and less so as the length of the panel study is increased. This is not to say that a long-term panel study may not have a set of specific objectives, and also general plans for meeting these objectives. However, conditions do change over time, resources may change, new ideas may arise from previous waves (if one is not careful...), and the priorities may be changed. Hence, while a general set of objectives is useful, it is also wise to stay flexible and be able to accommodate changes in objectives and procedures as they seem warranted.

Such changes are especially likely in a long-term research panel of the type that we shall describe very shortly. In such a case, there was the additional complication, that is not unusual for long-term panel studies, of a change in the funding sources, which can lead to changes in both the objectives of the study and the procedures.

In general, there seems to be somewhat of a tendency in the case of a research panel to place less emphasis on pure experimentation and to obtain more information on the techniques and methodology by means of observation and ex-post data analysis. This is not the place to indicate the various ways in which this may be done, except that we might note that this type of information can be obtained both internally--by studying the characteristics of the data--as well as by comparing characteristics and behavior of the panel with that of the population from which the panel was drawn.

The Illinois-Berkeley Panel

Background and Objectives

Three features make our consumer panels unique among studies of family economic behavior. The panel aspect is, of course, the primary of these. To date, 17 waves of data have been collected from the Decatur-Peoria panel, and 11 waves of data have been collected from the Chicago panel, creating two data sets which are rich sources of information about changes in family economic behavior and purchase decisions. Second, in these consumer panels, the family is not viewed as a single homogenous unit. Rather, it is regarded as being composed of individuals with separate backgrounds and personality characteristics which all influence family economic behavior to some extent. Finally, all couples in the panel are in the early stages of family formation and growth. This fact, together with the panel design, allows the collection of data from families while their economic and consumption habits are being formed and while many major life style events, such as the birth of children, migration, divorce, and remarriage are taking place.

Outline of the Panel Design

The consumer panels are two samples of young married couples who have been interviewed regularly since the time of their marriages. One of the panels consists of couples married in the summer of 1968 in Peoria and Decatur, Illinois. These sites were selected to avoid the complexity of a large city and to obtain respondents in sites which were reasonably self-contained economically and socially. At the time the panel was formed, the population

of these two cities was between 100,000 and 250,000, their economies were primarily industrial, and they were relatively isolated from other major urban centers, as is still the case.

The Peoria-Decatur sample was selected from a list of 1,300 couples who married in Peoria or Decatur between June 1, 1968, and September 30, 1968. Three sources were used to develop this list--county marriage license data from the three counties forming the Decatur-Peoria SMSA, newspaper accounts of new marriages, and records of clergy. From this list a sample of 400 newly married couples was selected, 150 in Decatur and 250 in Peoria. Addresses for these newly married couples were obtained by matching the last names with telephone directory listings or by contacting secondary sources, such as parents. Only couples who lived either in the Peoria or Decatur SMSA after their marriage were used. In addition, the husband had to be 30 years of age or less at the time of the marriage. The first wave of interviewing was completed in the fall of 1968, with 311 eligible couples completing the questionnaire.

When the Peoria-Decatur panel was four years old, the Chicago panel was formed, composed of young couples married in Chicago between June 1, 1972, and August 31, 1972. This sample was drawn from microfilm marriage records obtained from the Illinois Bureau of Vital Records. A sample of 1,003 couples married in Cook County was selected from this list. Location of the newly married couples' addresses was accomplished as in Decatur-Peoria, using telephone directory listings and information supplied by secondary sources. Only couples who lived within the Chicago SMSA after their marriage were eligible.

Four other eligibility criteria were imposed in Chicago:

1. The husband should be 30 years of age or less at the time of the marriage;
2. The marriage should be the first one for both members of the couple;
3. The couple could not own a home at the time of the marriage;
4. The couple's income should exceed \$5,000 per year, unless one of them was a student.

Since it was difficult to find couples who met all of these criteria, the first criterion was relaxed to include couples with husbands who were 34 years of age or less at the time of their marriage. The Chicago panel, first interviewed in the late fall of 1972, contained 409 couples.

Topics Included

Economic Behavior

The major purpose of these panels is to collect data on the durable goods ownership and financial assets of these young couples. For this reason, on each wave couples are asked about their purchases of durable goods during the time between interviews and their intentions to purchase durable goods during some specified period in the future. At regular intervals, information on their stock of goods is updated. For many of these goods, data are available on such characteristics as the price paid, the brand name, on whose advice the purchase was made, and who made the decision to purchase. Extensive information is also collected on the couples' financial portfolios, saving and budgetary practices, and use of credit. Many of the questions are geared toward determining the role of each marital partner in the decision making process.

Data relevant to the economic personalities of the spouses are also collected periodically. Both husbands and wives respond to questions by which they can be characterized as economically minded, price conscious, or bargain seeking.

Subjective assessments of the country's current and future economic situation, including inflation, have also been gathered from the respondents. Intermittently, the subjects have assessed their own economic situation relative to that of their parents, their friends, their own past, and their anticipated futures. Data on household income have normally been collected once a year.

Labor Force Participation

Data on additional economic characteristics relevant to labor force participation, such as occupation, industry, part- or full-time employment, and involvement in a second job have been collected at each interview. The surveys have also included an extensive number of questions relevant to female labor force participation (most of these after Wave 9 in Peoria-Decatur and Wave 3 in Chicago). These included asking nonworking wives about their reasons for not working as well as their own assessments of their occupational prospects if they were to seek a job, and the cost of child care arrangements they would incur by working. Working women reported on the cost that they actually incurred while working as well as their reasons for working. All women responded to questions on their work plans after having children and in the more general future.

Background Characteristics

A series of questions on the respondents' background characteristics was included in the first wave for each of the panels. These included birthplace, occupation of father, number of siblings, parents' marital status, and whether parents were currently living. Current religion and religious background were sought on a later wave.

Aspirations and Goals

Periodic attempts have been made to measure respondents' aspirations and goals. These have included educational, occupational, and familial aspirations, as well as financial aspirations. One wave also included questions on respondents' aspirations for their children.

Children

At each wave, respondents indicated whether they had a birth during the interval between waves. On the tenth wave in Peoria-Decatur and the fourth wave in Chicago, the exact dates of all births were obtained. This provided a check on earlier answers and filled in missing data for a few cases. Respondents also reported at each wave whether they were expecting a child or in the process of adoption. After Wave 6 in Peoria-Decatur and beginning in the first wave in Chicago, respondents answered questions periodically on their desired and expected family sizes. Respondents have also been asked about birth control as well as about abortion. On various waves, an attempt was made to review the decision-making process surrounding fertility.

General Attitudes and Personality Characteristics

Throughout, attempts have been made to measure general attitudes toward life and the personality characteristics of the respondents. Questions regarding attitudes toward life in general and satisfaction with one's own life and marriage have been asked repeatedly. Among other characteristics, measures of experiment-proneness, timidity, conservatism, and self-assuredness were constructed from responses to individual questions.

Sex Role Orientation

Both husbands and wives have responded periodically to questions concerning at what age and under what circumstances a mother/wife should work, the importance of job advancement, factors important in job selection, decision-

making concerning employment of other family members, and work histories of respondents' mothers. Husbands and wives have also been asked about the division of labor within their homes as well as those of their families of origin.

Time Use

Use of time for household tasks and leisure activities was the focus of a number of questions on Waves 8, 9, 12 and 15 in the Peoria-Decatur study and Waves 2, 3, 6 and 9 in the Chicago study. A series of questions about vacation plans and habits was asked of the Peoria-Decatur respondents on the eighth wave.

Social and Political Attitudes

Some topics reflect the political and social climate of the times in which they were asked. For instance, respondents' attitudes toward electric cars, reusable containers, and organically grown food have been assessed. Questions on transportation were asked during the energy crisis of 1973-74 and again on the current 1980 wave of the panels. Attitudes toward protests by blacks, students, and truck drivers were measured at the time truckers were blocking the highways. At the same time, questions concerning violence on television and police violence were asked. During earlier waves, questions on media preferences (newspapers, magazine, television) and exposure were asked.

This list represents a fraction of measures taken during the study and should not be regarded as exhaustive. Many of the topics just mentioned were covered on the spouses' separate questionnaires, so that answers are available from both members of a couple. In addition, many of the topics were repeated, so answers are available to the same questions at different points in time and after different durations of marriage. The table provided as an appendix summarizes selected data currently available for the consumer panel.

Response Experience

By June 1980, the Decatur-Peoria panel had been interviewed 17 times, and the Chicago panel 11 times. From 1968 until 1977, the aim was to interview both panels every six months. Beginning in 1978, the aim was to interview each of the panels once a year. Because of the vagaries of funding, it was not always possible to achieve these aims; thus, the actual intervals between waves of interviews varies between six and fifteen months.

The date of each wave of interviewing and the number of households completing interviews at each of the waves is shown in Table 1. From the first through the seventeenth wave, the total number of households in Decatur and Peoria dropped from 311 to 206. The reduction in the number of cases was even more severe in the Chicago panel, which lost over half of its members from the first to the tenth wave, dropping from 406 to 194 cases. As expected, attrition was most serious during the earlier waves of the panel, due largely to couples refusing to participate or inability to locate couples who had moved.

We were concerned that such attrition represented an important source of bias in the consumer panel. To measure this bias, we conducted a follow-up study of nonrespondents in 1975, making intensive efforts to locate and obtain completed interviews from a sample of people who had left both panels. We found the dropouts of these consumer panels differed only slightly from the current panel members. The relatively high rate of attrition, particularly for the Chicago panel, appeared to have had very limited effects on the demographic structure of the panel. Significant differences between panel members and dropouts did appear in relation to expenditure characteristics, in particular to the ownership of various durable goods. However, even

here, no discernible pattern of bias emerged.

Experience with Sensitive Information

The focus of these panels is family financial decisions. Extensive information is collected on the couple's financial portfolios, saving and budgetary practices, use of credit, and ownership of life insurance. Many of these questions are highly sensitive, asking for the value in dollars of specific assets and debts. Our experience with item nonresponse for such items parallels our experience with attrition; that is, the rate of item nonresponse has dropped over the life of the panel. For example, item nonresponse to household income was .3 percent on the seventh wave of the Peoria-Decatur panel and .9 percent on the first wave of the Chicago panel. On the most recent wave of each of these panels, nonresponse to this item had dropped to .2 percent.

We believe that item nonresponse has dropped for several reasons. First, those most likely to refuse sensitive items have already left the panel. Second, over the years, the panel respondents have come to trust our guarantee of confidentiality. Periodically, we issue special reports to respondents, summarizing some of the findings of the study. In reading through these reports, respondents discover that we do, in fact, report their responses as aggregate estimates, and that it is not possible to identify individuals on the basis of what we report.

Third, in 1977, the method of data collection was changed from face-to-face interviewing to telephone interviewing. When we made this switch, we were concerned that it would depress response rates and possibly increase item nonresponse. In fact, it did not. We found that respondents were less reluctant to report dollar amounts when interviewed on the telephone, possibly because this form of data collection had the effect of making interviews more objective by insulating respondents from the interviewer.

Experience with the Use of Incentives

Because the panel members are asked to do a substantial amount of record checking during the course of an interview, we give them a small gift each time they are interviewed. When respondents were interviewed face-to-face, the interviewers presented the gift at the conclusion of the interview. Now that respondents are interviewed by telephone, gifts are mailed in advance to each panel member. The monetary value of these gifts is small, ranging from \$2 to \$5 per couple. However, we feel the psychological value of the gift is important both for minimizing attrition and item nonresponse.

Some Uses of the Data

Because the consumer panels are ongoing projects, analysis to date has been somewhat limited. Most of it has been done using data from the Peoria-Decatur sample, since the Chicago marriages are still of relatively short duration. The analysis which has been done has concentrated on two major areas--various facets of family financial behavior, and fertility and female labor force participation.

Very briefly, some of the principal findings from these studies may be summarized as follows:

Family Financial Behavior

1. The studies support the idea that family financial behavior can be better understood if the family is treated as interrelated individuals rather than as a homogeneous unit. In their analysis of asset accumulation by the Peoria-Decatur couples, Ferber and Nicosia (1972) found that while

education of both the husband and the wife influenced asset ownership, the effects of education for the wife tended to be in the opposite direction from that of the husband. In addition, the effects on asset accumulation of some personality variables and individual's priority on savings also tended to work in different directions for husbands and wives.

2. Ferber and Lee (1974a) found that who played the role of the so-called Family Financial Officer (FFO) did not appear to be determined by socioeconomic characteristics of the couple, but rather by savings attitudes and economic personalities. Most frequently, the couple acted jointly as the FFO; however, over time there was a pronounced shift toward the wife's assuming this role. The identity of the FFO did appear to influence economic behavior. For instance, when the husband was the FFO, the proportion of income saved was greater than when the wife alone or the couple acting jointly played this role.

3. Lee and Ferber (1977) found tendencies for assets to be greater when the husband and wife acted jointly as the FFO. They also found that when wives worked the family had less debt. However, the couples best off financially after five years of marriage in terms of net assets were those who were venturesome enough to acquire substantial amounts of debt. In this sample, both debts and assets primarily related to the purchase of a home.

4. Ferber and Lee (1974b) have attempted to integrate lifestyle into their model, believing that lifestyle may provide an additional dimension beyond the socioeconomic role and personality variables studied to date. Operationalizing lifestyle according to time use, they classify couples into lifestyles on the dimensions of career orientation, pleasure orientation, and familial orientation. Findings indicate that lifestyle helps to explain why women work and whether couples purchase automobiles.

5. Several additional papers by Ferber and his associates (Ferber and Lee 1973; Liebman and Ferber 1977; Nicosia and Ferber 1976) have been concerned with the ability to predict purchases of certain durable goods from responses to questions on past purchases, satisfaction with current goods, and the likelihood of purchasing of goods in the future. The most recent paper of the three (Liebman and Ferber 1977) found that later actual auto purchases were related to earlier predicted and current auto purchases.

6. Anderson and Nevin (1975) found that demographic, socioeconomic, psychographic and other variables were relatively weak predictors of household life insurance purchasing behavior. They reasoned that this was due in part to the exclusion of life cycle change as an explanatory variable, since they used data for the first one or two years of marriage only. They did find that six variables were significant in explaining the amount of life insurance purchases.

7. Lee and Ferber (1980) in a further study of life insurance acquisition found that three variables were significant in explaining the type of life insurance purchased. The purchase of term insurance was found to be much more likely in households where the net worth was large; the wife purchased term insurance before marriage; and the insurance agent did not influence the couple's decision.

Fertility and Female Labor Force Participation

8. Several papers using data from the consumer panels have concentrated on the determinants of fertility behavior. In "Relative Status and Fertility" Crimmins-Gardner and Ewer (1978) tested the relative income hypothesis, that fertility is affected by the relationship between desired and actual living levels. Relative status was measured as the difference between the husband's occupation and the occupations of both the husbands' and the wives' fathers.

Also, each spouse compared his (her) family financial situation at the age of 16 to the couple's financial situation at marriage, in the seventh year of marriage and with the expected situation in the seventeenth year of marriage. When these measures of relative status were related to fertility, only the wife's subjective assessment of relative status showed a consistent and significant pattern. Wives who felt they were or would be better off than their parents, want more children than wives who compare their own situations unfavorably to their teenage years. hypothesis that people with certain backgrounds which emphasized children over material possessions have children earlier relative to the time they acquire material goods (when income is controlled) than people without these backgrounds. Occupation and religion were the two background characteristics examined. However, the results showed that occupation and religion have little effect on the timing of the first child, the purchase of durable goods, or the relative timing of these two acquisitions. Income does affect when people acquire goods, both absolutely and relative to children. Couples with higher incomes acquire goods absolutely earlier, and earlier relative to the birth of the first child. This last relationship is the result of both earlier goods acquisition and later births of first children in couples where the wife works.

10. A panel design is particularly appropriate for investigating the causal dynamics underlying the negative relationship between working and fertility. Data from the first seven years of the Peoria-Decatur panel were used in a path analysis to disentangle the effects of husband's income, wife's education, wife's age at marriage, family size, and wife's employment and subsequent time intervals (Ewer, et al., 1979). The results indicated that during the early stages of marriage and family formation the presence of young children exerted a strong negative effect on wife's employment. In contrast to this effect of fertility on employment, the effects from employment to fertility are less consistent.

11. In an additional study, only wife's labor force participation was used as the dependent variable (Crimmins-Gardner and Ewer 1978), to explain factors affecting employment among young mothers. In addition to the usual determinants of working, expenditures connected with working and the emotional cost of child care were important determinants of the labor force behavior of young mothers.

12. Bagozzi and VanLoo (1978a, 1978b, 1979), have begun to develop a theory of fertility as consumption, examining two classes of socioeconomic determinants--economic variables and social structure variables. The socioeconomic determinants are hypothesized to act as exogenous variables, either facilitating or constraining psychological and social decision-making processes within the family. These latter processes are posited to be the primary endogenous variables affecting fertility.

Tests of the overall theory were performed on three separate samples using a structural equation methodology. In general, fertility decisions were shown to be affected directly by the social psychological processes within the family and only indirectly by socioeconomic constraints, as predicted.

If We Had To Do It Over

Recounting these experiences and results leads us to raise a final question that is likely to be of general interest, namely, if we had the opportunity to do this panel study over again, would we, and how would we change things?

First, would we do it over again? Certainly--the topic is fascinating, the study design is full of challenges, and the results seem to be both very useful and personally rewarding. On the other hand, we would also certainly want

to make various changes in the study design. Some of these changes are pretty obvious, such as having a larger sample size and interviewing panel members every six months on a regular basis, something that we could not always afford. Indeed, interviewing the panel members in a study of this type every six months initially, say for the first five years, and every year thereafter would seem just about optimal, based on our experience.

Some of the other changes are perhaps less obvious, such as the following:

1. Even with separate interviewing of both spouses (a highly desirable approach for data collection purposes), we would have started using the telephone approach much earlier than we did. Our experience, as well as that, for example, of the Health Interview Survey of the U.S. National Center for Health Statistics, indicates that such simultaneous interviews can be obtained very efficiently by telephone. Personal interviews would still be used the first couple of times, and would also be used where families are not reachable by telephone, but the principal reliance would be on the telephone approach.
2. We would seek more powerful methods of maintaining panel member cooperation. This could range anywhere from sending more letters and reports between interviews to introducing an incentive system similar to that of the commercial panels where the rewards for remaining in the panel increase geometrically with the length of time. However, there would certainly be problems in doing so, given the University sponsorship and likely limitations on funds.
3. Insofar as possible, we would develop at the outset a clear set of objectives for the types of decision problems that we wished to study, or hypotheses to test, and develop a long-run data collection plan based on such objectives. Unfortunately, this is more easily said than done. Because funding sources change, there is always uncertainty regarding future funding, and even with a fixed set of objectives, one's ideas how to best obtain the necessary data change with time and with experience.
4. Last but not least, we would take our programmers and systems analysts, lock them in a room, and feed them only mashed potato sandwiches and warm water (or, worse yet, milk), until they came up with a simple and economical means of putting these data in a computer file that is amenable to analyses both over time and over space. Getting a manageable file that would permit the many uses to which panel data could be put is one of the most frustrating aspects of a panel operation. In fact, we are not sure that we would put the mashed potatoes into the sandwiches until the programmers were close to a reasonable solution of this problem.

Thank you.

TABLE I

N.A. = Not Available

¹Panel members who have moved outside of the Peoria, Decatur, or Chicago SMSA since the initial interview are sent mail questionnaires. In addition for Waves 1 - 14 of the Peoria/Decatur Panel and for Waves 1 - 8 of the Chicago Panel, the male and female heads of the household each received separate self-administered questionnaires.

OVERVIEW OF THE CONSUMER EXPENDITURE SURVEYS ^{1/}

N. Gail Hoff, Bureau of the Census

General

The United States Government has recently begun a statistical program to provide current data on consumer expenditures of the population. Until now, there have been periodic surveys but no continuing program to provide such data on a regular basis. This gap in the government's statistical program has hindered many important analyses of the interrelationships of income and expenditures for various population groups, has created a lack of means to keep the Nation's Consumer Price Index more current, and has caused a void in studying and measuring the effects of a broad range of important policies and programs on the population such as inflation, taxes, energy, housing, medical care, and so on. After many unsuccessful attempts in the past, the Bureau of Labor Statistics (BLS) received appropriations in fiscal year 1979 to develop and conduct an ongoing Current Consumer Expenditures Surveys Program. The project has been given high priority by the Secretary of Labor. The program consists of three interrelated surveys; the two expenditure surveys are designed to provide the expenditure data for revising the expenditure item weights and for studying family buying habits; the Point of Purchase Survey provides data on the outlets at which people shop, to be used in updating the outlet samples for the BLS consumer pricing surveys.

In addition to producing the data necessary to update the CPI market baskets of goods and services and to revise the CPI weights, there are many other uses of the data. Some of these uses are to (1) provide a continuous flow of data on income and consumption patterns for use in economic analysis and policy formulation, (2) provide one of the basic data inputs required to revise and update the BLS Family budget program as required by the Comprehensive Employment and Training Act of 1973 (CETA), and (3) provide a flexible consumer survey vehicle that will be available for use by other Federal Government agencies.

The Census Bureau is responsible for the survey design, data collection and processing activities for the program.

The surveys were last conducted during the period of 1972 through 1974.

This paper will present an overview of the operational aspects of each of the surveys and point out any significant differences with the earlier surveys.

Sample Design

Data in the two expenditure surveys are collected from a national probability sample of households designed to be representative of the total civilian noninstitutional population. A sample of 102 primary sampling units (PSU's) was selected, 86 of which have been previously defined and selected by the BLS for the CPI revision. These 86 PSU's represent the urban part of the United States with the additional 16 PSU's added to represent the rural population. Only the 86 urban PSU's are used in the Point of Purchase Survey.

The unit for analysis for all three surveys is the set of eligible individuals comprising a consumer unit. A consumer unit consists of all members of a housing unit or other type of living quarters who are related by blood, marriage, adoption, or some other legal arrangement. The consumer unit determination for unrelated persons is based upon financial independence.

The sample design for the Quarterly Interview Survey will be a rotating panel scheme. Interviews with each sample unit will be conducted quarterly over a period of five consecutive quarters (15 months) and then dropped from the survey. The first interview for a household will serve to "bound" data for expenditures and to obtain information on the household composition and characteristics of its members. Data collected in the initial survey quarter will not be included in developing the regular series of expenditure estimates. Data collected during the second through fifth interviews will form the basis of the estimates derived from the quarterly survey. After the fifth quarter in sample, the panel will be dropped from the survey and replaced by a new incoming panel. The quarterly sample will be divided into three equal parts with each part designated for interviewing in a particular month of the quarter and every 3 months thereafter while in sample. The monthly sample consists of approximately 2,360 assigned units.

This scheme differs markedly from the 1972-73 survey, partly because it is a continuing survey rather than a one-time survey. In 1972-73, approximately 23,000 addresses were selected in 216 PSU's. Half the sample was introduced in January 1972 and half in January 1973. Each yearly sample was in the survey for five consecutive quarters.

The survey methodology for the Diary Survey requires each selected sample unit to keep two 1-week diaries of expenditures over two consecutive weeks. The earliest possible day for placing a diary with a household will be pre-designated so that each day of the week has an equal chance to be the start of the reference week. The annual target sample size at the United States level for the Diary Survey is 5,470 completed interviews with a total estimated workload of 7,700 sample units. During the last 6 weeks of each year, the Diary sample will be supplemented to twice its normal size (about 850 of the above designated units) to increase the reportings of types of expenditures unique to the holiday season. The basic difference between the current Diary survey and the one conducted in 1973 and 1974 is again a one-time survey versus a continuing one. One additional difference is in the assignment of a first possible placement day. In the previous survey, each sample unit was assigned a week for placement, with the effort made to place the Diary as early as possible in the sample week. Results of the 1973-74 survey showed that the amount of expenditures reported was highest during the first day of the recording period regardless of what day of the week the first day was and tended to taper off towards the end of the 7-day period. By attempting to control the first day of the recording period, each day of the week has an equal chance of being selected as the first recording day. This should spread any reporting bias resulting from calendar day placement among all days of the week.

^{1/} This paper cannot be copyrighted. It may be reproduced.

Preliminary results of the relationship between the earliest placement day assigned for a diary case and the actual day the diary was placed show that 62 percent of the diaries are placed by the third day and 72 percent are placed by the fourth day. This indicates some difficulty in placing a diary on a specific day.

The sample for the Point of Purchase Survey is a clustered systematic national sample of housing units in 86 SMSA's or ZIP code areas across the country. These areas will be treated essentially as PSU's. The program will be designed so that the entire 86 areas in the sample will be updated every 5 years, approximately one-fifth of the PSU's will be surveyed each year. In the first year, 18 of the PSU's will be surveyed. Each year for the succeeding 4 years, a different fifth of the areas will be sampled. In the sixth year, the cycle will begin again. Through the 5-year cycle, 29,000 units will be surveyed. The only difference between the 1974 survey and the current survey is the spread of the PSU's across 5 years. This was done mostly for financial reasons.

Quarterly Interview Survey

Data Collection

The Quarterly Interview Survey is designed to collect data on certain types of expenditures which respondents can be expected to recall fairly accurately for periods of 3 months or longer. In general, expenses reported in the survey are relatively large, such as purchases of property, electrical appliances, and vehicles, or are expenses which occur on a fairly regular basis, such as rent, utility bills, or insurance premiums. The purpose of the Diary Survey is to collect information on the small, inexpensive items which respondents cannot be expected to recall even for relatively short periods of time. Most of the items for which estimates will be derived from the Diary Survey are not sufficiently covered, or are not included at all in the Quarterly Interview Survey. Data collection began in October 1979.

Each occupied Quarterly Interview Survey sample unit will be interviewed once per quarter for five consecutive quarters. In the first interview, information will be collected on socioeconomic characteristics of the household, an inventory of major durable items, and expenditures for selected goods and services during the reference period. Since the initial interview is meant to serve as a bounding interview, the reference period for expenditures is kept to 1 month in order to reduce the amount of interview time. Since duplicate reporting is most likely to occur in the period closest to the interview, the 1-month reference period should provide an adequate period for bounding purposes. A uniform questionnaire with a 3-month reference period has been designed for interviews 2 through 5. Replacement households in interviews 2 through 5 will be unbounded and have a 3-month reference period.

The exact reference period which will be used in all interviews after the first will be from the first of the month, 3 months ago, up to the time of interview. Although this allows the reporting of expenditures for slightly longer than a 3-month period and creates overlaps in reference periods, it is preferable to collect purchases made during the month of interview at this time since recall will be the shortest and most accurate of these purchases. Because of the intentional overlap in reference periods, it was necessary to develop a technique for bounding the data in order to control for duplicate reporting of

expenditures in subsequent interviews. Bounding also prevents the reporting of expenses in a current reference period which actually occurred during an earlier period. As stated previously, the first interview's data will be used primarily to bound data reported in subsequent interviews. To prevent duplicate reporting from one quarter to the next, a method was developed for the pretest which has been implemented for the ongoing survey. For most purchases reported, the date of purchase and a description of the item is obtained. At the completion of the interview, the field office will transcribe the information reported for selected items onto designated areas of the next quarter's questionnaire for the sample unit. The interviewer then has the previous quarter's responses available for bounding purposes at the next interview.

The inventory technique is also being used in the Quarterly Interview Survey to improve the accuracy of reporting. An inventory of certain items, such as owned property, major household appliances, automobiles, and insurance policies possessed by the household, is obtained at the initial interview. The inventory serves as a launching point in subsequent interviews, reminding the respondent of any additional or replacement purchases of such items made since the time of the initial interview.

In addition to the initial interview questionnaire and the uniform quarterly questionnaire for the second through fifth interviews, there will also be annual supplemental questions which will be asked at the fifth interview. These questions will obtain more detailed income information for the past 12 months--cash receipts, taxes, contributions, occupational expenses, and detailed mortgage payment data. Another of the differences in methodology between the 1972-73 survey and the current one is the way the data is collected. In the 1972-73 survey, the reference period was not constant as it is now, but varied for different kinds of expenditures.

In the 1972-73 survey, the first interview collected information on socioeconomic characteristics of the household, an inventory of major durable items, and expenditures for selected goods and services purchased since the first of the year. The second, third, and fourth interviews focused primarily on relatively inexpensive items, such as utilities, clothing, small durable goods, household furnishings, vehicle operating expenses, and the like. Data on income received during the preceding year also is collected during the second quarter's interview. The fifth and final interview obtained data on income, assets, and liabilities for the survey period, as well as expenditure data for most items covered in the survey.

The recall period for reporting expenditures varied according to the size and frequency of the expenditure class. Frequent and relatively inexpensive items, such as utilities, clothing, and vehicle operating expenses, were collected at quarterly interviews. Slightly more expensive items, such as small kitchen appliances and furniture, were collected using a 6-month recall period. For very expensive and infrequent purchases, such as real estate, automobiles, and major appliances, the recall period was 12 months.

One of the reasons for such a change in the collection methodology is the estimation procedure to be used. In 1972-73 only annual estimates were produced, with all data collected referring either to 1972 or 1973. In the current survey, "quarter of occurrence" estimates will be produced. This will require that data collected in a 5 consecutive-month period be used for

such estimates. For example, expenditure data for the October through December quarter will be collected in the November, December, January, February, and March interview months. For this reason, data must be tabulated by the particular month of the reference period in which the expenditure was reported to have occurred. For some characteristics, this will not be possible as expenditures are not reported by month but are provided either in aggregate figures for a 3-month period or by an average expenditure pattern over time such as monthly or weekly costs. The BLS is exploring different methods of allocating the reported 3-month aggregate expenditures or the expenditure pattern data to individual months within the reference period.

One of the primary concerns in the Quarterly Interview Survey is the accuracy of the expenditure data reported. It is unlikely that any respondent could accurately report all of the detailed information requested without referring to records of some type; however, pretest interviewers estimated that only 50 percent of all respondents used any records at all during the interview. Encouraging respondents to keep records for the quarterly visits in the ongoing survey will continue to be an important part of the program. Attractive calendars and files will be offered to respondents; interviewers will be trained to persuade respondents to keep records; and a letter will be sent before each quarterly visit to remind respondents of the type of expenditures they will be asked about.

Data collection is under the direction of the Census Bureau's permanent professional field staff, operated through 12 regional offices throughout the United States. Each staff member is thoroughly trained prior to beginning his/her work on the survey. Initial interviewer training consists of 3-1/2 days of classroom training plus self-study training. A 2-day classroom training session was held prior to the start of the second quarter with subsequent self studies and classroom sessions being provided as needed. In addition, a 1-1/2 day supervisor's training session was held prior to interviewer training.

Data Processing

In 1972-73, all clerical and computer processing was performed at the completion of the five quarters of interviewing at a centralized location. Since quarterly estimates are a necessary part of the ongoing survey, a different method of processing had to be developed. Although a number of alternatives were discussed, the most feasible was decentralized processing in our 12 regional offices.

When the questionnaires are returned to the offices, they are clerically coded for household and consumer unit relationship, make and model of automobile, trip destination, and detailed codes for type of housing repairs. In addition, all outlets (insurance companies, schools, etc.) are coded uniquely by name. Upon completion of the clerical processing, the data are keyed using a Nixdorf data entry system and transmitted to Washington via communication lines where it passes through a very detailed computer preedit. Inconsistencies, errors, and identification of missing questionnaires are transmitted back to the regional offices for reconciliation by the field staff through office review or interviewer followup. Corrections are then keyed and transmitted to Washington and cycled through the computer preedit. This continues until errors identified by the preedit no longer appear. Once a panel month's preedit is complete, data necessary for bounding is transcribed to the next quarter's questionnaire. The current quarter's

questionnaire is sent to our processing office in Jeffersonville, Indiana, for microfilming and storage.

Industry and occupation coding is completed via computer listings sent to Jeffersonville; the codes are keyed and transmitted to Washington to be merged into the main data file.

The data then goes through a rather complex computer edit. In addition, demographic and work experience items are imputed when missing or invalid. The file is then run through an adjustment to net out business and reimbursed expenses; adjusted to always include sales tax and then weighted.

For interviews 2 through 5, an inventory management system is being developed in order to show expenses for items identified using the inventory technique for which payments are still being made at the same level.

The BLS will be provided with both monthly and quarterly weighted tapes beginning in June 1981, for the first calendar quarter of 1980.

Diary Survey

Data Collection

The purpose of the Diary Survey is to obtain expenditure information for small, relatively inexpensive items which are subject to severe recall loss and for which the Quarterly Interview Survey collects only cumulative expenses or does not cover at all. Expenditure classes not sufficiently covered in the Quarterly Interview Survey include food and beverages, personal care products and services, small household supplies, and a few other relatively inexpensive items.

The survey methodology for the Diary Survey calls for each selected sample unit to keep 1-week diaries of expenditures over each of 2 consecutive weeks. The earliest possible day for placing a diary with a household is predesignated so that each day of the week has an equal chance to be the starting day of the reference week.

Respondents are asked to report all expenditures made during the recording period, not just those which will be used for CPI revision purposes. The main reason for this is to take away from the respondent the decisionmaking about which items to record in order to reduce the chance of error due to the respondent's confusion over whether to record an item. It was felt that this additional recording would not increase the respondent's burden for reporting, since the vast majority of the items reported are those of interest to the survey.

The interviewer makes three visits to the Diary household over the 2-week period. At the first visit, the interviewer conducts a brief interview with the household respondent which includes obtaining the household composition and selected demographic characteristics of each member. The interviewer then explains to the respondent how to keep a diary, the type of detail that is needed, and where to record the information. The interviewer then makes an appointment for 1 week later. At that time, s/he returns to the household and reviews the first diary for completeness and legibility, updates the household composition, and asks a few selected questions regarding common types of expenditures. The third appointment is made, again for 1 week later. When the interviewer returns for the

third visit, the second diary is reviewed and selected questions on income and work experience are asked.

If the interviewer arrives to pick up the diary on the appointed day, and the diary has not been completed, the expenditures for the week are obtained through recall. The interviewer would mark a box on the front of the questionnaire to indicate the Diary was completed by the recall procedure. However, if the Diary is not picked up on the appointed day, the expenditures cannot be obtained through recall.

Because the weekly Diary workload is so small, interviewers in the Quarterly Interview Survey also work on the Diary Survey. A 3-day training session was held prior to the start of the Diary Survey and included concentrated instructions on concepts common to both the Quarterly and Diary Surveys as well as training for the Diary Survey. This was done to shorten the Quarterly classroom training which has traditionally been 5 to 7 days.

A 1-day supervisors' training session was held prior to interviewer training. Any additional supervisor or interviewer training will probably be combined with that for the Quarterly Interview Survey.

Data collection for the Diary Survey began in September 1979, using the product-structured diary which is composed of a similar set of adjoining pages for each day of a 7-day period. The pages are structured by product category headings to aid the respondent in recalling and recording purchases made during the week.

Data Processing

When Diary questionnaires are returned to the offices, they are checked in and reviewed for completeness and consistency. Any problems are immediately referred back to the interviewer. The questionnaires and diaries are then shipped to a centralized processing location (Jeffersonville) for coding and data keying. The data is then transmitted to Washington where a computer preedit is performed to identify errors resulting from coding and keying. Any remaining errors are corrected and rekeyed.

A computer edit for consistency is then performed along with the imputation of missing or invalid demographic or work experience data. As in the Quarterly Interview Survey, adjustments are made to include sales tax. However, since the respondent is asked only to report personal expenditures, no adjustments have to be made for reimbursed expenses. The data is then weighted. Monthly data tapes will be provided to the BLS beginning in February 1981.

Point of Purchase Survey

Data Collection

Data collection procedures are similar to those used in the 1974 survey, with modifications to the item checklists and to the recall periods for certain expenditure items. The survey is conducted over a period of 4-6 weeks beginning in April of each year. Each consumer unit is interviewed once. The field work takes place under the direction of the Bureau of the Census' permanent field staff operated through the 12 regional offices and the Washington field staff.

Each staff member is thoroughly trained prior to beginning work on the survey. Interviewers will receive 2 days of classroom training plus 8 hours of self-study training materials. Formal training is

supplemented by on-the-job training as necessary to ensure job performance at a level of established standards.

The interview itself consists of two major parts. In the first part, the interviewer elicits information on the demographic and socioeconomic characteristics of the household. Then the interviewer conducts the second part of the interview, which consists of the checklist and questionnaire administered together. The checklist, a list of consumer goods and services, is sectioned into a number of different recall periods. The respondent identifies the items on the checklist which the household has purchased in the stated recall period. Then, the interviewer requests information about all outlets at which a particular type of purchase was made. The name and location (including the closest intersecting street) of each store at which items were purchased and the costs of the items are collected. The interviewer then proceeds to the next items with the same checklist/questionnaire procedure, until the interview is completed.

There are two separate checklists, but only one is administered to a given consumer unit. The checklists are split to reduce the reporting burden for each consumer unit. Unlike for the 1974 survey, there is considerable overlap between the two checklists with respect to the items included. The recall period on each of the checklists varies from 1 week to 5 years depending on the relative frequency and expense of the purchase. A shorter recall period is used for the more frequently purchased items, such as foods and gasoline, whereas a longer period is employed for less frequently purchased and more expensive items, such as major equipment items or vehicles.

At the end of the day's interviewing, the interviewer codes as many of the store names obtained during the day as possible. An alphabetized, precoded computer list of retail, wholesale, and service outlets in the area is provided for this purpose. When possible, the interviewer matches the exact store name and address obtained in the interview to one on the list and codes the outlet accordingly. Those outlets which cannot be coded from the list are coded in a centralized operation at the Bureau's Jeffersonville operation's office.

Data Processing

In the precomputer processing, all store names not coded in the field are coded. A card file is created to code stores which do not appear on the coding list. The processing of the final Store Code List comprises a major portion of the data processing. BLS has requested that outlets retain the same code from one year to the next. This involves matching codes for two lists compiled 5 years apart, since each PSU is to be interviewed only once every 5 years.

The remaining precomputer and computer processing is similar to that performed in the 1974 survey. After check-in, general and specific coding and verification, data keying, precomputer editing, and reject processing, the computer processing will take place. This involves reformatting and editing, matching coded stores back to the original list to obtain additional geographic detail, and weighting the final records. A microdata tape is delivered to BLS by September 30 of each year.

Preliminary Results

Currently, the only results available from the Quarterly Interview Survey or the Diary Survey are

field response rates, inasmuch as the computer processing system is still in the developmental stages. The Point of Purchase Survey is conducted only for internal use by the BLS, so again only data on the collection activities are available.

Quarterly Interview Survey

Response rates in the first 9 months of the survey are quite pleasing and compare well with the 1972 survey. Tables 1 and 2 show response rates by month and by quarter for the current survey and the 1972 survey respectively.

Although the initial response rate of 90.2 percent for the first quarter is somewhat lower than 1972, by the end of the third quarter, the difference is less than one-half percent. In the third quarter, the response rate of 88.6 percent is only 0.4 percentage points lower than 1972. However, it should be noted that the current survey has rotation groups at various interviews, i.e., first through third interviews, whereas in 1972, all were in their third interview. But given the general decline in response rates in the past few years, the current survey would appear to be doing well.

Diary Survey

Response rates during these first several months have been considerably lower than expected. Although they are comparable to those obtained in the 1972 survey, they are considerably lower than those obtained in the 1973 survey. (See Table 3)

During the first 4 months (September-December), the cumulative response was 78.2 percent, with the rates ranging from 93.4 percent to a low of 59.0 percent among the 12 regional offices. The highest response rate for any week during this period was 84.9 percent for Week 10, and the lowest rate was 58.2 percent for week 17.

Since the sample is an annual sample, the weeks start again with the beginning of each year and response rates are cumulated on a calendar basis. As of Week 21 for 1980, the cumulative response rate is 82.8 percent with the highest rate reported being 90.9 percent in Week 12 and the lowest rate reported being 69.4 percent in Week 21. There is an overall improvement of about 4.6 percentage points in the 1980 work to date over the rate obtained in the 1979 period, with most of this improvement being noted during the last several weeks.

One of the main reasons for the improvement in the response rate is the increased emphasis and stressing the importance of the Diary Survey to the regional office staff. In addition, interviewers are requested to contact the offices earlier in the placement week when they encounter refusals, that the supervisors must make a better effort to convert refusals, and that we keep constant watch over the rates, getting back to problem offices on a timely basis. Probably the most important effect of our efforts with the field staff has been their placing more effort on contacting households within the allotted time.

When the supervisors were brought together in February, special emphasis was put on the noninterview problem. Supervisors from offices with low Type A rates spoke on methods they use to deal with the problem.

Point of Purchase Survey

The Point of Purchase Survey has just completed its fourth year.

A comparison of response rates for 1974 and 1977-80 are shown in Table 4. The 1980 response rate of 94.9 percent is only 1.6 percentage points lower than when first conducted in 1974. Almost all of the change can be observed in a corresponding increase in the refusal rate.

TABLE 1
Response Rates by Month and Quarter
Quarterly Interview Survey

Month/Quarter	Response Rate	Noninterview Rate	
		Total	Refusal
October-December 1979	90.2	9.8	7.5
October	89.8	10.2	7.8
November	90.9	9.1	7.1

CONSUMER EXPENDITURE SURVEY DATA: USES BY BLS

Eva E. Jacobs, U.S. Bureau of Labor Statistics

Abstract

Consumer Expenditure Surveys conducted by the Bureau of Labor Statistics provide essential data for BLS statistical series as well as for general economic analysis and making purposes. Use of these data by BLS in the CPI, expenditure tables, and Family Budgets as well as the differences in concept among the series are described.

The long history of consumer expenditure surveys in the United States reflects the variety of needs which they were designed to serve, which have generally been associated with the need for cost of living information. The inquiries over time have been directed to the welfare of immigrants in 1870, the influence of the costs of living on the cost of production in connection with setting tariffs in 1888, the incorporation of the data as weights in the Consumer Price Index and the use of the data in developing Bureau of Labor Statistics (BLS) Family Budget cost estimates. BLS has always published tables, and more recently tapes, of expenditure, income and asset data to permit users to track changes in consumption patterns and to examine the relationship among economic variables for different types of families. The words "different type of families" cannot be overemphasized because it is the provision of demographic characteristics associated with the economic data that is the major contribution of this survey. This is in contrast to the other widely used measure of consumption, the personal consumption expenditure component of the national accounts, which is an aggregate estimate of consumption of all families in the U.S. and does not tell us who is buying what.

The survey data are essential to several major BLS programs and I will describe how these uses affect the design of the survey.

For the Consumer Price Index (CPI), the data are used for the derivation of the expenditure weights of the components and for the selection of items to be priced. Since the 1977 revision, the CPI has been constructed for two populations. One is the total urban population, about 80% of the total non-institutional population. Derivation of weights for this group requires expenditure data and geographical identification. The other is for the traditional concept of urban wage earner and clerical workers, about 40 percent of the population. The determination of this group requires data on geography, occupation, employment status, and income because the group is defined as limited to certain occupations based on the proportion of income derived from these occupations.

The particular definitions of the CPI components determine to some extent the kinds and number of questions that are asked in the survey. It is not enough to ask the respondent for his monthly mortgage payment although the response may well be reliable and might be sufficient for certain types of analyses of outlays. Homeownership cost in the CPI includes the net cost of houses purchased in the base period and the interest cost contracted for over half the term of the mortgage. In order to estimate these weights it is necessary to know the price of houses purchased and sold, the interest rate contracted for, number of years, down payment, etc.

Some components require additional detail because of experience with price movements. Telephone charges provide an example. Since intra-state and interstate prices may move differently, expenditures for long distance and local service are treated as separate items. It is not sufficient to know what the total telephone bill was for CPI purposes.

The requirements of the CPI change over time and the change in the 1978 procedure for selecting the detailed item to be priced for the CPI has allowed us to reduce some of the detail collected. Prior to the revision, BLS pricing agents were given detailed descriptions of items to be priced. These items were selected from the detail collected in the survey. In the new disaggregation process the agents have more general descriptions to choose from. For example, previously the pricing agent was given a specific type of toaster to price - all agents attempted to price the same specification. Now the agent is provided with the item "small kitchen electrical appliances." Through the disaggregation process, which involves the relative sales of items in the store, the pricing agent selects the specific item, a toaster, in one outlet, a can opener in another. Since this procedure was introduced after the 1972-73 survey, the question was changed for the continuing survey from asking about a long list of items, all of which are frequently responded to with "no", to a question that asks about small kitchen appliances.

This may be satisfactory for the CPI but may prove to be a great disappointment for marketers of small electrical appliances. This is part of the constant conflict between the desire for more and more data and the desire to reduce respondent burden. Other requirements for the CPI have added new kinds of questions to the continuing survey. With the 1977 revision of the CPI, a separate point of purchase survey was introduced from which the sample of outlets which agents visit to collect prices for most components is drawn. For certain components, such as telephone and gas and electric utilities, the name of the company supplying the service is now obtained in the expenditure survey. The responses will form the basis for selecting outlets for these components in the future. However, point of purchase information may not be made available for individual outlets because of CPI confidentiality requirements.

The second major activity in the Bureau concerns use of the data for general economic analysis of consumption. The Bureau has published a series of tables which shows selected characteristics, expenditures, income and assets and liabilities for all families and families classified by income, age, family type, region, etc. From these for example, one can compare the consumption patterns of the elderly with the general population, or the prime working age group. Or one can compare one earner husband-wife families with two earner families. For this use even more data are required than for the CPI since the CPI does not cover income taxes, social security taxes, life insurance, cash gifts and contributions. All of these are included in a family's outlay and clearly influence the amount that will be spent for consumption items. Assets and liabilities come into play since borrowings or asset depletion are used to finance expenditures and loan repayments and additions to assets constitute additional outlays.

The methodology and format of the 1972-73 survey were markedly different from past surveys and these new features had a considerable impact on the process of developing the published tables. In earlier surveys, the household's income, total expenditure and assets data were collected through an annual recall procedure. The 1972-73 survey provided for two surveys -- one, consisting of a quarterly interview of one sample covering major expenditures and another, consisting of a separate sample keeping a two week diary from which frequently purchased components such as food detail and household supplies could be obtained. The new form had some inherent problems. One complication was that the time periods covered in the two surveys were not the same, although there was an 18 month overlap. That was finally resolved through a deflation procedure for the diary portion to provide an estimated two year period to match the interview. There was an additional difference in the time period covered by the income question. Since income is one of the most important variables in the tabulations, it was necessary to make an adjustment to make the income variable in the diary comparable with the interview. These adjustments having been made, the two surveys were integrated by groups of consumer units. For example, the food component of diary families of four persons were combined with interview families of four persons to form the four person family column in the integrated table showing expenditures by family size.

What was learned about changes in consumption shares from 1960-61 to 1972-73? The major movement was away from food and towards transportation for all segments of the population. The exception was that the food share increased at the lowest income level, probably as a result of the food stamp program. These were the expected results, since food shares have been declining since the 1930's, but the extent of the change in transportation was greater than expected. For all consumer units, total food declined as a share from 24 percent to 20 percent even though expenditures for food away from home were increasing. While for the total population this was partly the result of the decrease in family size, the decline was significant for all family sizes. The increase in the transportation share from 15 to 21 percent is associated with more cars per family as well as increased use. This trend held across the board for all types of families. The fact that the share for transportation now equals or exceeds that for food, is a graphic confirmation of the importance of the automobile to the American lifestyle.

In addition to published tables, we make available micro data tapes. However for the tapes the problem of the two surveys has not been solved -- separate tapes are produced for each survey. For many users who wish to analyze a particular component such as gasoline, there is no difficulty -- the interview tape is self-contained with all its associated characteristics. For researchers wishing to have a micro record of all expenditures, however, there is a problem, for matching individual diaries to individual interviews is much more complicated than matching by group. I don't know of anyone who has undertaken this activity as of now.

In BLS, expenditure data also have been used in the construction of the 4-person family and retired couple's budgets. These are hypothetical constructs that estimate the amount of income that is required to live at three specified levels of living -- lower, intermediate and higher. The 1960-61 survey was used as a basis for determining the long list of goods and services which constitute a significant portion of the budget estimates.

There has been a good deal of criticism of the methodo-

logy of the current budgets and at the very least, the market basket should be updated to reflect 1972-73 data.

A committee of experts was appointed to advise BLS on revising the budget program. The committee's report is now being reviewed. The major recommendation was to establish the level of adequacy as the median expenditure of the 4 person family as being a reflection of the prevailing American standard of living. If the recommendations in the report are adopted, the Bureau's new Continuing Consumer Expenditure Survey will provide the basis for establishing this standard in the future.

I have briefly described three data series published by BLS which measure levels of, differences in or changes in what is popularly known as living costs, all of which use Consumer Expenditure Survey data. Furthermore, because all three series provide data for selected areas as well as the U.S., they are widely used to satisfy the great demand for information on differences in living costs among areas. Since the differences in what each is designed to measure are not always clear to users the data are frequently misinterpreted. I will briefly describe the differences in concept among the series.

First, the family budgets, because it is the series most widely used for interarea comparisons of living costs. These costs represent differences in cost of living among areas at a point in time. The budget market baskets are not the same in all areas -- there are variations in many of the components. These have not been changed since 1967, but the consumption costs are updated through time by the components of the CPI for the particular area. Therefore, only the change in prices since the base period affects an area's relative position in subsequent periods.

The CPI measures the change in prices over time in each area and is often considered to be a measure of the change in the cost of living over time. A more rapid increase in the CPI between any two periods of time in one area versus another does not mean a higher cost level in the second period but simply a more rapid escalation of prices in one area. However, if one area's CPI increases more rapidly than another over a long enough period, its living costs will eventually reach a higher level even if those costs started at a lower level.

The published tables from the Consumer Expenditure Survey for selected metropolitan areas describe what people actually spend in those areas. The differences in expenditures for an area result from different characteristics of the populations as to income, age, ratio of homeowners and renters, price levels and taste. Thus, we are measuring what people do in these areas rather than how living costs vary.

In addition to the basic difference in what these series are designed to measure, there are differences in definition of particular components, most notably in the treatment of homeownership cost. This component has recently been receiving a good deal of attention in connection with the CPI. While homeowner costs are a very large component of living costs, the concepts of measurement and comparability are difficult and there does not appear to be a consensus as to the "correct" way to measure such costs.

Since the family budgets are supposed to represent an established family, they include the cost of owning a home purchased six years earlier, so that mortgage payments and interest costs are calculated for a mortgage obtained six years earlier than the budget year. This clearly is not relevant to someone just moving into the

area or a young family purchasing a home for the first time. The CPI, on the other hand, includes as a weight in its market basket the net purchase of home (in the base period) and the interest costs for half the term of the mortgage for those consumers entering into mortgage agreements in the reference period. These are then moved by changes in house prices and interest rates. These changes in the housing component clearly are not relevant to homeowners who purchased home years before. In our publication of data from the expenditure survey, we present still another concept of homeownership costs, this time in terms of the total household current account and balance sheet. The current costs for all homeowners for interest, taxes, insurance and maintenance, are included in current consumption but principal payments are considered repayment of a loan and are shown as a reduction in liabilities with other loan repayments. This concept of consumption costs might not suit someone who wanted to know how much they needed to earn to cover current outlays.

Users need also to be aware of the concepts and coverage of the expenditure survey data in making comparisons with other data sources. The comparison most frequently made is between the survey data (CEX) and Personal Consumption Expenditures (PCE) in the national accounts. Such a comparison should not be made without adjusting for differences in concept which affect the shares, the aggregates and the trends over time. Significant differences exist in the housing, automobile, health care and financial components. For example, rent in PCE is space rent, in CEX contract rent; homeowner costs in PCE are estimated from rental equivalent values, in CEX an outlay approach is shown; new automobiles are gross in PCE, net of trade-ins in CEX.

These cautionary words are intended not to discourage but to enhance understanding of the data and thereby help make analytical results more reliable. While the surveys provided essential information for government policy making and statistical activities from the start, marketing interest in the data has been more recent -- from the 1960's, when Life Magazine funded an extensive publication produced by the Conference Board based on the 1960-61 data. For the 1972-73 survey we have sold tapes to over 300 universities, individual companies and other research workers in addition to thousands of copies of the published bulletins. We anticipate even wider use of the results of the continuing survey than of the past sporadic surveys.

The Continuing Consumer Expenditure Survey is not in the field and we are looking forward to getting the first tapes from the Census Bureau. Our review and publication plans are being formulated now. We plan to release regular quarterly and annual publications based on the integrated diary and interview data. However, because of the infrequency with which individual items are purchased and the smaller sample size, the quarterly expenditures will be highly aggregated and the number of characteristics quite limited. On an annual basis, both the detail and the number of classes of classifying characteristics can be increased. Deriving reliable data may require aggregating two or more years of data. In addition to providing timely data on consumption patterns, the survey data will eventually be very useful in evaluating the need for and timing of revisions of the CPI market basket.

We also plan to make public use tapes but specifications of content or frequency are not yet available.

It is not until we review the data that we will be in a position to recommend changes in the questions or the

methodology. We hope to introduce a research panel on which proposed major changes will be tested but that is for the future. The goal is to provide useful, reliable and timely information.

AN EVALUATION OF THE METHODOLOGY OF THE
1972-73 U.S. CONSUMER EXPENDITURE SURVEY ^{1/}

Robert B. Pearl, Survey Research Laboratory
University of Illinois

Abstract

This paper evaluates the accuracy/quality of various types of expenditure data collected in the 1972-73 Consumer Expenditure Survey. Recommendation for changes in the methodology - some of which already have been implemented by the Census Bureau, are made.

Introduction

Collection of data on consumer expenditures is probably the most widespread of all statistical endeavors in this country, engaging both the public and private sectors. Such information is, of course, virtually the lifeblood of the market research industry. The Government is also heavily involved in this field for a variety of purposes. Expenditures by consumers constitute one of the principal components of the Gross National Product accounts. Data on outlays for food, housing, and other living costs are an essential ingredient in establishing benefit levels for social programs. Perhaps most important, this kind of information provides the technical framework for construction of consumer price indexes.

Although the objectives and type of detail may differ a great deal among these various public and private undertakings, many of the technical problems are common to all. In particular, nearly every survey organization has experienced serious reporting errors and biases in attempting to collect information from consumers about their purchasing behavior. This is one reason the findings from the large-scale Government expenditure survey conducted in 1972-73 should be of general interest to practitioners in this field and to others who use or could use similar techniques.

The 1972-73 Survey comprised two major components:

(1) An interview panel consisting of about 10,000 households each year which was visited on a quarterly basis primarily to obtain the larger items of expenditure and certain repetitive items (rent, utilities, etc.) Particular categories were covered either quarterly or on a semi-annual or annual basis, depending primarily on expenditure size.

(2) A diary operation consisting of about 200-250 households per week asked to keep a diary or record of all expenditures for the subsequent, two-week period. Although the main focus of the diary was the smaller items of expenditure, the fact that all categories were covered provided various options in compiling estimates as well as many research opportunities. For further information on the methodology used for this survey, see other papers presented in this session.

^{1/} This work was undertaken under a Joint Statistical Agreement between the Survey Research Laboratory and the Research Center for Measurement Methods of the Bureau of the Census.

Purpose

Because of the critical uses which are being made or which could be made of the data and the marked changes in methodology, considerable attention has been devoted to evaluation of the survey results. The objectives have been to assess the adequacy of the survey procedures in general, the relative merits of using interviews as compared to diary keeping for particular categories of expenditures, and the implications of the findings with respect to improvements in methodology for future use in either a continuing survey program or other similar undertakings. Since there was little prospect that all of the methodological issues would be resolved, a determination of further research needs was also an important goal.

This paper presents a summary of the findings and conclusions deriving from this evaluation effort. Detailed results appear in publications in the Census Bureau's Technical Paper Series (Nos. 45 and 46).

Summary of Findings for Expenditure Categories

The following is an attempt to assess the adequacy of the expenditures data obtained in the 1972-73 survey for the various categories of goods and services. The general approach used in this appraisal has been to compare the estimates from the quarterly panel with those from the diary operation, where the same subject was covered in both, and to relate either or both to various independent sources of expenditure data. The principal objectives are to assess which of the survey procedures appeared to be more effective for particular categories of expenditures and to determine what types of improvements and modifications may be suggested by the results. The conclusions can only be tentative because of major uncertainties about the validity and comparability of the independent data used as a standard and because adequate detail was often unavailable to explore the subject in sufficient depth. Nevertheless, in a substantial number of cases, persistent patterns emerged across category lines which pointed in rather specific directions.

The most frequently used of the independent data sources are the Personal Consumption Expenditure (PCE) estimates prepared by the Department of Commerce in conjunction with the Gross National Product Accounts. The other independent data derive mainly from Government administrative, census, or survey sources although some private sources are also used. In some sectors, such as education and health, the conceptual differences between the PCE and the 1972-73 survey data were such that dependence had to be placed entirely on the other independent sources for comparative purposes.

It should be noted that the survey results used in this evaluation are derived from special tabulations of re-weighted original data tapes. They do not reflect editing charges which may have been made at later stages of processing by BLS. As a result, the figures may differ somewhat from those already published or to be published by that Agency or which may be compiled from the public-use data tapes recently issued. Certain differences in time reference and conceptual approach would also contribute to the disparities.

Table 1 presents a summary of the findings for the various expenditure categories. For purposes of summarization, a number of the detailed categories have been combined and averaged. The table designates the "best" survey source, that is, the one generally closest to the independent data, in cases where the two survey estimates are significantly different. The ratios of the "best" survey estimates to the independent estimates are indicated in terms of broad class intervals, allowing insofar as possible for conceptual differences between the sources, but the actual computed values are also provided. Although the magnitude of these ratios may provide some indication of the adequacy of the survey estimates, the margins can be regarded only as rough approximations, for reasons stated above, and have been used primarily for purposes of detecting any consistent and meaningful patterns which have a bearing on the methodology.

1. Food and beverage expenditures--After allowance insofar as possible for various conceptual incomparabilities, there appeared to be a reasonably close correspondence between the diary estimates of food purchases for home use and the independent sources. The fact that the homemaker--the usual diary keeper for the family--is ordinarily responsible for most of the purchases was undoubtedly a positive factor. The allocation of maximum space on the diary record to this expenditure class probably contributed as well.

There were considerable disparities, however, in the precision with which various food categories were reported. The reporting was apparently most complete for relatively costly items, such as meat and poultry, and for those used promptly and on a daily basis, such as milk, eggs, fruit juices, and bread and fresh-baked items. The coverage seemed to be considerably less complete for food staples which are bought less frequently, with each purchase used over a considerable period of time. One of various possible explanations for these differences is that many respondents may not start keeping their diaries promptly--or do not make entries, as requested, on a daily basis--but later attempt to reconstruct the omitted periods by memory. In doing so, items which represent the main course in a meal or which are purchased and used relatively frequently might be more readily recalled.

A less anticipated finding was the close correspondence between the survey and independent estimates for meals in restaurants or other eating places, where a substantial proportion of the outlays would be made by individual family members other than the homemaker. The prominent positioning of the section for reporting purchased meals on the diary record and some emphasis to this subject at the time of the diary checking procedure might have contributed to this outcome. At the same time, the marked deficiency for alcoholic beverages confirms the continued failure of household surveys to measure a sector where there is considerable sensitivity about reporting.^{2/}

2. Small expenditures other than food--For various small expenditure items other than food, for which the diary was the principal if not only source, a predominant factor appeared to be the role of the various family members in making purchases. Where the responsibility was principally that of the homemaker, such as for laundry or cleaning products or household services, the reporting appeared to be considerably more complete than in cases

^{2/} Some special check questions, asked at the time diaries were collected in an effort to overcome this deficiency, provided data that would have increased the survey estimates by about 15 percent (no actual correction was made, however). Even on that basis, the survey aggregates would have amounted to only about half of the independent levels.

where other members were substantially involved, as for toiletries or hair care. Even for those expenditures where the homemaker predominated, however, the reporting appeared to be generally less adequate than for food purchases, probably partly a reflection of the much smaller amount of space and attention given to non-food items on the diary record. Some limited efforts to measure small non-food expenditures through summary questions in the quarterly panel did not appear to be especially productive, although in one or two cases the figures appeared to be more complete than the weakest of the diary estimates.

3. Clothing expenditures--As was anticipated to some extent, this expenditure category represented one of more troublesome sectors, with neither survey source exhibiting any clear cut overall advantage and neither corresponding very closely with the independent data.^{3/} Following the pattern observed throughout the analysis--and expected from previous experience--the larger items (suits, coats, etc.) were apparently more adequately reported and the quarterly panel emerged as the superior source in this case. Also not surprisingly, the diary procedure represented the "best" source for a diversified category such as accessories, where it was probably difficult to communicate the full range of items in an interview procedure. For no apparent reason, the diary estimates also provided the closer correspondence with the independent data for footwear, although this subject was probed in much greater detail in the quarterly panel.

For the broad range of middle and lower priced clothing products, the advantage seemed to alternate between the two survey sources, without any consistent relationship to the importance of the item. One problem which complicated the appraisal--and which extended to most other expenditure classes as well--was the existence of a large residual clothing group in the diary estimates, consisting mainly of incomplete or inadequate entries which could not be assigned to specific categories.

4. Household appliances--Reporting of expenditures for major appliances was apparently one of the more successful survey outcomes. The high cost associated with these items and the more probing nature of the "inventory" technique, described earlier, probably contributed to this favorable showing.^{4/} There was some evidence in favor of pooling the two estimates obtainable for a given year under this approach, the one based directly on the survey for that year and the other derived indirectly from the initial inventory in the survey for the following year. Comparison between those two sets of estimates indicated no significant differences for several of the major appliance groups and no evident superiority of one over the other in relation to the independent data. Pooling of the estimates would have roughly the effect of doubling the sample size at virtually no additional cost, a considerable gain for items with especially large variances.

The picture was considerably less favorable for small appliances, which would be consistent with the findings for other product categories. The inventory approach is

^{3/} Clothing expenditures were covered each quarter in the interview panel. Some 16 broad categories were specifically probed, using detailed item checklists for each. A small section was provided for clothing expenditures on the diary record and it was, inadvertently, located in an especially inconspicuous position on the form.

^{4/} The inventory was updated only once, at the final quarterly visit, for large appliances. The updating occurred twice, at 6-month intervals, for small appliances.

apparently less successful where a multiplicity of small products is involved (such as for small kitchen appliances) or where the family may possess several articles of the same kind (e.g., cameras or radios). An interesting by-product of the inventory approach in these instances, however, was that estimates which included the value of gifts received from outside the household--which derived directly from the inventory on items on hand--invariably exceeded those which included the cost of items bought by the family as gifts to be given to others, which was based on their recollection of purchases. This finding suggests that the inventory method, based on items in the family's possession, has certain advantages over the more conventional approach which requires recall of previous actions.

5. Household furnishings--This broad category provided a rather clear-cut demonstration of the relationship between the size of an expenditure and the likelihood of its being reported.^{5/} The closest correspondence with the independent estimates was found for furniture, the most costly class, followed by the next most significant group--floor, window, and furniture coverings. In both cases, the quarterly panel appeared to be the superior source, partly on the basis of sampling variances. The survey estimates fell considerably short for household linens and especially for smaller products such as dinnerware and cookware, luggage, and decorative items. In these latter instances, the diary estimates, although themselves deficient, appeared to be at least equivalent in coverage to those from the interview panel.^{6/}

6. Automobile and vehicle expenses--In most categories, the survey data corresponded closely with the independent sources. The main disparities were for tires and other accessories. Although the homemaker would normally have less responsibility for vehicle expenses than most others, the diary estimates held up surprisingly well for some of the smaller categories, especially gasoline. The quarterly panel, as expected, was clearly the superior source for vehicle purchases and also appeared to provide the more reliable data for vehicle registration, insurance, and similar items.^{7/}

7. Housing expenditures--Once again, with the exception of one rather diffuse category (fuel purchases), the survey and independent estimates corresponded rather closely.^{8/} Also, in the main, the diary-based data, again

^{5/} Most items in this class were covered at 6-month intervals in the quarterly panel. The exception was household linens which were covered each quarter. A small section was provided on the diary form for "housewares, furnishings, hardware, and garden supplies."

^{6/} In fact, for the dinnerware-cookware category, the diary estimates were appreciably higher and, thereby, closer to the independent levels.

^{7/} The "inventory" approach was used for vehicle purchases in the interview panel, with the inventory updated only once at the final quarterly visit. Questions were asked each quarter, however, for gasoline purchases and vehicle maintenance and repair. A section was provided for "gas, oil, tools, parking fees, and other vehicle expenses" on the diary form.

^{8/} A rather complex set of procedures, including use of the "inventory" approach in some cases, was used to determine housing expenses in the quarterly panel. For home repairs and maintenance, detailed questions (adapted from the Census Bureau's special survey on this subject) were asked each quarter. Utilities were also covered each quarter using the "last payment" approach (asking for the amount of the last bill and the period it covered). A section for "rent, utilities, fuel, phone, insurance" was provided on the diary record.

unexpectedly, matched those from the interview panel. The exception, in the case of mortgage payments, may have resulted from the fact that some such disbursements are made directly through bank accounts, which could easily escape the attention of the diary keeper.

8. Health expenditures--One of the more pleasant surprises was the relatively close correspondence between the survey and independent estimates for most health expenditures, usually considered to be one of the more treacherous areas in this kind of undertaking.^{9/} A less optimistic reading might be that the survey results were at least as good as most previous endeavors of a similar nature, without attempting to categorize their accuracy in an absolute sense. In any event, the diary procedure once more provided the most unexpected outcome, in that not only for small items such as drugs and medicines, but also for most professional health services, the data seemed to hold up surprisingly well. An exception was for hospital services but even the quarterly panel data in that instance seemed somewhat deficient, possibly because of complications introduced by the pervasive role of health insurance and other third-party payors.^{10/} Also, for health insurance premiums themselves, where the interview panel data appeared to be reasonably adequate, the diary procedure was understandably ineffective, in view of the fact that payments are often made through payroll deductions which would rarely come to mind in completing a household diary.

9. Education, travel, and miscellaneous expenses--Because of the diversity of items, it is more difficult to summarize for this remaining expenditure group.^{11/} Although the evidence was limited, there appeared to be some deficiency in reporting of education expenditures, possibly because of the difficulty of adequately covering college students in a household survey. The quarterly panel still appeared to be the better source for the larger payments (tuition, etc.), but it seemed desirable to alter the survey procedures for students attending college away from home, whereby they would be interviewed directly at their college quarters instead of obtaining proxy information, in some instances, from their parents at home. No direct comparisons were possible for other school expenses, but it appeared likely, based on other findings, that the smaller expenses--books, school supplies, meals outside of school, boarding arrangements, etc.--as well as related items, such as recreational lessons, might better be approached through the diary procedure.

^{9/} Detailed inquiries were made in the interview panel at 6-month intervals for health expenditures. A section for "personal care, drugs, and medical supplies" was provided on the diary form but other medical expenses would presumably be entered in the catch-all section.

^{10/} The survey objective was to measure "out of pocket" costs, net of insurance and other reimbursements.

^{11/} Education expenses were covered at 6-month intervals in the interview panel. Detailed inquiries were made each quarter on trips and vacations. Other items were covered at various intervals depending on expenditure size (but with a quarterly inquiry for watches and jewelry). Most of these items were not specifically mentioned on the diary record.

Comparisons with independent sources for travel and vacations could only be made in terms of the reported number of trips taken rather than directly for expenditures. On this basis, the quarterly panel data appeared to be consistent with other findings. Since the validity of expenditures data may depend more on whether or not an expenditure is reported than on the precise amount of the expenditure, even this limited finding with regard to trips taken could be meaningful.

For the remaining subjects--transportation costs and miscellaneous products and services--a few generalizations may suffice since the patterns appeared consistent with those already cited for items of a similar nature. Public transportation expenses, which were available in detail only from the diary, were drastically underreported in relation to the independent sources, probably because such outlays are usually made on an individual basis. Among the miscellaneous categories, the larger items, such as pianos, organs, and funeral expenses, were much more adequately reported in the quarterly panel and the survey estimates agreed, in large measure, with the independent data. A large disparity for watches and jewelry could have resulted, in part, from sensitivity in reporting such expenditures, whereas a similar deficiency for moving expenses could reflect some undercoverage of recent movers in the survey.

Conclusions and Recommendations.

The survey findings, although predictable in a number of respects, carry some implications for further efforts in this field, not only on behalf of Government programs but possibly for market research and similar private endeavors. A rather unexpected result was the relatively effective performance of the diary procedure in some sectors, such as housing and health, where the quarterly panel has been assumed to be the only realistic option. The diary results also appeared to be about as effective as those from the quarterly panel in many cases where both sets were evidently deficient, including some situations where a great deal of attention had been devoted to expenditure reporting in the interview procedure.

A general rule of thumb suggested by these findings might be that, unless a clear-cut reason existed for using an interview procedure such as the quarterly panel, dependence might better be placed on diary-keeping for purposes of expenditure data collection. The diary might be a dubious source for items with exceptionally large variances (vehicles, appliances, furniture, etc.) or where unusual payment arrangements might require special questioning, such as insurance paid through payroll deductions, mortgage payments made automatically through bank accounts, hospital bills paid largely but belatedly by insurance, etc. The diary might also be inferior to an interview process in cases where a composite set of questions may be necessary in obtaining complete responses as may be the case, for example, in cataloging trips and vacations. In other instances, the diary procedure appears to be at least as good a risk as the interview approach, and probably a less costly one as well.

A number of modifications and improvements in the diary procedure are clearly necessary, however, in order to overcome some rather evident deficiencies. Some possible steps in this direction are the following:

1. Limit the range of items any one family would be asked to report--The use of a diary covering all items of expenditure, as was done in the 1972-73 Survey, may have certain theoretical benefits, but considerably proscribes the ability to improve the overall process

sufficiently to satisfy the expanded requirements just cited. Evidently, as stated earlier, one of the reasons for the more successful coverage of food purchases than other small items in the 1972-73 diary was the much greater amount of space and attention accorded the former. Moreover, for all categories including food, there was a considerable undifferentiated residual group, resulting mainly from incomplete or inadequate entries which could not be classified in detail, which detracted materially from the usefulness of the results. The general lack of space and the inability of interviewers to focus on so wide a range of items in reviewing the diaries probably largely accounted for this latter deficiency.

Most market research endeavors and similar undertakings are already restricted in terms of item coverage. However, since exhaustive detail is often requested about specific items (type of packaging, package sizes and weights, brand names, ingredients, marketing features, etc.), it is possible that better results would be obtained if the samples were split and particular respondents were asked to report on only a subset of products. For more comprehensive projects, such as the 1972-73 Survey, where the amount of detail is more limited, a possibility would be to split the sample along category lines. One subsample, for example, might be asked to report only on food and the supermarket products, a second on clothing and household linens, a third on health expenditures, etc. There is obviously some practical limit to the number of subsamples that could be simultaneously operated and a good deal of thought and some experimentation would be necessary to derive a workable plan.

Probably even more important than space considerations, the use of this kind of specialized approach would make it feasible to provide for a more focused set of check questions and procedures at the time of diary pickup to overcome some of the disparities noted in the present survey (such as underreporting of certain food items relative to others). In fact, a modified procedure would likely entail much more of a combination of interviewing and record keeping than is now the case. A good deal of developmental work would be required in devising effective checking procedures.

2. Vary length of record-keeping periods--As previously noted, the 1972-73 Survey provided for two weeks of record keeping for each sample family, covering all items of expenditure. In most private undertakings also, the practice is to use a standard reporting period for those products which are covered. If specialized subsamples are developed as proposed above, it is obvious that either a larger overall sample would be needed or much higher sampling variances would have to be accepted. One way out of this dilemma would be to vary the length of the record-keeping period depending on the variances of the subjects covered for a given subsample. For example, for a low variance category, such as frequently purchased food items, a period as short as a week might be adequate. For most categories besides food, however, such as clothing or health expenditures, record keeping periods of up to 3 months or longer might be considered. The fact that only a limited set of items is covered might reduce the reporting burden sufficiently to secure extended cooperation of this kind without an unacceptable attrition in the sample.

In such a system, the use of less costly collection methods already employed in many private endeavors, such as having respondents mail in completed diaries on a periodic basis (monthly, semi-monthly, etc.) would be more practical. Provision would, of course, have to be made for follow-up (by mail or telephone, where possible) for non-respondents or to carry out special checking for returns that did not meet prescribed standards.

3. Provide separate diaries, where indicated, for individual members--As noted, only one person, usually the homemaker, probably maintained the diary for the entire family in the 1972-73 Survey. Not surprisingly, the results were clearly more favorable for the kinds of expenditures for which the homemaker was mainly responsible than for those likely to be made by other members. One possible way of obtaining more consistent results, where the expenditures to be reported are of a more dispersed nature, would be to provide separate diaries for all family members above a certain age (perhaps 12 and over) on which to record their individual disbursements. For this purpose, the diaries could be briefer and less formal than the main record for the family. Experimentation with various versions would obviously be important in developing a procedure of this kind.

4. Providing monetary or other incentives for cooperation--Most market research endeavors provide various cash or non-cash incentives to promote greater cooperation. There is considerable reluctance to follow this course in Government surveys, although the approach is not unknown. In fact, an experiment with cash incentives was conducted in the early stages of the 1972-73 Survey to determine whether cooperation could thereby be improved. The results were inconclusive in this regard and the incentives were dropped from the procedure. As noted earlier, cooperation was high in spite of the absence of material rewards.

Since most studies have shown that the quality of reporting as well as the degree of cooperation appear to be benefitted by some type of material inducement, the matter of providing incentives should be seriously considered in any operation where there is primary dependence on diary keeping. The rewards should, of course, be attuned as closely as possible to achieving the main objectives. If, for example, it is important for individual family members to keep separate records, the incentives should be offered only if all such members agree to cooperate, which would presumably promote intra-family pressure for individual compliance. Similarly, if cooperation over extended periods is requested, a useful approach is to offer a small reward for each sub-period with a sizeable bonus for completing the entire cycle. Special consideration for prompt and complete returns by mail (where used) might be still another element. Payment of incentives might also be made contingent on retention by respondents of cash register tapes, bills, and other evidences of expenditures which could be consulted in reviewing the diaries.

5. Continue exploration of timing biases--Although not mentioned up to this point, perhaps the most conclusive survey finding was affirmation of the traditional bias found in diary operations, whereby a higher level of expenditures is reported in the earlier as opposed to the latter stages of the record keeping period. In a 2-week diary procedure, for example, the estimates for the first week are almost invariably higher than those for the second week. Differences of this nature were found for virtually every expenditure category in the 1972-73 survey. The margins of difference varied a good deal, however, and seemed to be almost random in nature. There was no evident relationship of the weekly differences for a category to other survey measures, such as the completeness of reporting relative to the independent estimates.

Since separate pages were provided in the diary for each reporting day, it was possible to examine the day by day recordings in this context. It was found that the higher levels for the first week diaries were primarily the result of exceptional amounts of expenditures recorded for the first reporting day (about 40-50 percent above the daily average). Levels were also above average

for the first day of the second diary week (8th reporting day) but not nearly to the extent found in the first week. There was a tendency for a gradual decline in expenditure levels in the course of each week. There were indications that this pattern persisted for most categories of expenditures.

Although various theories have offered for this phenomenon, the one that appears most likely on the basis of the evidence is that there is a certain amount of "telescoping" of expenditures on the first day. According to this theory, many respondents may not begin their diaries immediately, but skip the first day or two and then attempt to reconstruct the information from memory. In doing so, they may inadvertently include some expenditures made prior to the reporting period. Another suggestion that the patterns can also be attributed to some element of fatigue as the period lengthens can also be supported by the findings. Still another hypothesis to the effect that respondents may alter their buying habits temporarily because a diary is being kept does not appear to be supportable as a major element because the differences are so widespread among categories.

Among the suggestions made to control for this tendency is to extend the period of reporting somewhat (such as to 17 days for two-week diaries) and then to exclude the entries for the early and final days from the estimation. Another is to conduct a brief retrospective interview covering a day or two prior to the reporting period and to use that information as a "bounding" or control device in examining the early diary entries. The problem with such procedures is that, by reducing the impact of the exceptional diary levels at the outset, they would accentuate the tendency for understatement in the overall diary levels in general. The better approach might be first to attempt improvements in diary reporting through various of the possibilities cited earlier in order to be able to afford the use of any devices for controlling telescoping.

6. Explore use of universal product codes--A promising technological development that could affect future survey work in this field is the inclusion of "universal product codes" on most canned and packaged supermarket and drug store items (and likely to extend to many others). A useful experiment would be to ask respondents to record these codes in their diaries where available, as well as brief product descriptions, to assess how accurately this information is reported. If the effort is sufficiently productive, respondents might be relieved of the necessity of describing products in any detail where code numbers are available. More importantly, this step could result in far more accurate and consistent classification of products reported in surveys and a major reduction in the coding effort required at the data processing stage.

A related effort would be to make more effective use of the much more descriptive cash register tapes now being provided in automated checkout systems. If retained by respondents, they could certainly augment and, in some cases, take the place of diary entries.

In a comprehensive expenditure data program, such as required for purposes of the Consumer Price Index, there would be need for an interview survey capability, especially for high variance items, even if greater dependence were placed on a diary procedure. An interview approach would also be the indicated procedure in market research surveys related to durable goods and similar products. The main lesson from the 1972-73 Survey was that exhaustive interview surveys are likely to be self-defeating in this sector, and that the inquires at any one time should be limited to those products and services not amenable to the diary technique. The use and possible extension of the so-called inventory approach for

durable goods was also generally supported by the findings. Also confirmed was the notion of using variable time references in interviews depending on the size and importance of particular items.

One final matter might be mentioned which has a bearing primarily on comprehensive surveys such as those conducted by the Government, but which would be of interest to analysts of consumer behavior in general. The major recommendation made--curtailing the scope of the interview phase and introducing specialized diaries--would mean that only very partial expenditure data would be available for individual families, either for annual or shorter periods. Unless some counter measures were taken, there would be some evident limitation in the ability to analyze individual consumer behavior.

Actually, some of the largest items, which distinguish one family's expenditures from another's, would still be obtained by interview under these proposals for periods up to a year, but most categories would not be covered. A first step to close the gap might be to add a few questions, perhaps on an annual basis, to identify exceptional expenditures in other sectors, such as large orthodontic bills, major house additions, purchase of expensive paintings, and the like.

Beyond that point, a further although admittedly experimental step would be to obtain certain limited information in the interview procedure on behavioral patterns which would help in imputing data from the diary operation or another source to the individual family record. For example, in the health sector, questions could be asked on the frequency of doctor or dental visits, consistent usage of costly drugs, etc., which, together with demographic and socio-economic characteristics, could provide a basis for imputing a value for health expenditures to the family from another source. (The other source would, of course, also require the inclusion of such behavioral items.) Obviously, considerable research and testing would be needed before embarking on a large-scale endeavor of this kind.

TABLE 1

Summary of Findings for Expenditure
Categories: 1972-73 Expenditure Survey
Estimates Compared to Independent Sources

*Signifies that comparisons are based on 2 years of data. For other categories, comparisons were based on only 1 year, usually 1972.

1/ The "best" survey estimate is defined as the one--quarterly panel or diary estimate--which was closest to the independent figures. Where a double asterisk (**) is appended to the code, this indicates the specified source was the only one for which a comparison with the independent estimates could be made in the required detail. In most of these latter cases, the specified source was also the only realistic source for the data in question.

2/ The ranges in this column are not always entirely consistent with the computed ratios in the next column, but attempt to make allowances for conceptual differences between the survey and independent sources, disparities among the independent sources themselves, and other factors for which numerical adjustments could not be made.

3/ The ratios are based on weighted averages of the survey data (numerator of ratio) and of the independent data (denominator of ratio) for the various individual categories combined on a given line of the table. Where the two survey estimates were not significantly different (Code "N" in the "best" survey source column), the quarterly panel and the diary data were averaged. Where more than one independent source is specified, those data were averaged for this purpose. Revised ratios reflect PCE data adjusted to 1972 benchmarks. Preliminary ratios based on PCE data projected from 1967 benchmarks (and used in the preliminary evaluation report--Census Technical Report No. 45).

4/ The independent sources, in alphabetical order, are as follows:

AHS--Annual Housing Survey, Bureau of the Census; A. M. Best--Insurance company premium data compiled by A. M. Best and Co.; Cen-Bus--1972 Census of Business Merchandise Line Data; Cen-Serv--1972 Census of Selected Service Industries; CHAS--Center for Health Administration Studies, University of Chicago; ERS--Economic Research Service, U.S. Dept. of Agriculture; HIS--Health Interview Survey, National Center for Health Statistics, U.S. Dept. of HEW; MRCA--Panel data from the Market Research Corp. of America; NCES--National Center for Education Statistics, U.S. Dept. of HEW; NTS--National Travel Survey, Bureau of the Census; PCE--Personal Consumption Expenditures, CNP Accounts, U.S. Dept. of Commerce; SSA--Social Security Administration, U.S. Dept. of HEW; SORAR--Survey of Residential Alterations and Repairs, Bureau of the Census.

5/ Uncertainty about the magnitude of a conceptual difference precludes a more precise judgment for this borderline value. The ratio of the survey to the independent estimate is understated because the PCE figure used as a base relates to "off premise" consumption and includes (in addition to food purchased for home use) snacks purchased in stores (and other establishments which are not eating places) but consumed outside the home. The survey estimate, however, relates only to food purchased for home use. The reverse situation holds for the PCE and survey estimates for "purchased meals and snacks" where the ratio is overstated.

6/ This is an average value for the eight major categories included in this bracket. Of these, three were significantly more completely reported than indicated by the coded mean value, but there was no clear-cut distinction among these by expenditure size.

7/ Using optimum estimate (including value of gifts received and averaging the two alternative estimates for the year), see text. Under the standard estimation, the rating for major appliances would be "A, B" but that for minor appliances would be "D".

8/ Survey estimates used in the computation were diary estimates for dinnerware-cookware and hand tools and average of the two estimates for decorative items and luggage.

9/ Computed ratio is understated (magnitude uncertain) because the PCE base figure (but not the survey estimate) includes fuel used in rental quarters which is supplied and directly paid for by the landlord.

10/ Comparison based on college tuition only.

11/ Comparison based on number of trips taken rather than expenditure.

12/ Uncertainty about allocation of a large unclassifiable residual (about 15 percent of transportation expenditures) precludes a more precise judgment for these categories.

THE CONSUMER EXPENDITURE SURVEY: PROSPECTS FOR CONSUMER RESEARCH

Gregory D. Upah, Virginia Polytechnic Institute and State University
Seymour Sudman, University of Illinois

Abstract

This paper provides a brief overview of methodological changes in, and particular benefits of, the Consumer Expenditure Survey as they relate to prospects for consumer research. The major focus of the paper is to point out some of the major issues/research questions which can be addressed through the use of the C.E.S. data.

As early as 1965, there were major attempts to stimulate increased interest in longitudinal and other types of over-time studies of consumer behavior (Andreasen 1965; Granbois and Engel 1965; Nicosia 1965). However, to date there have been few such efforts undertaken and reported in the literature by consumer researchers. While such research is widely done by industry sponsored research groups (e.g., The Conference Board), major marketing research organizations and major retail and manufacturing firms, seldom are these results published and/or available to consumer researchers not associated with these organizations (for exceptions, see Linden 1965 and Linden and Axel 1978).

The Consumer Expenditure Survey sponsored by the Bureau of Labor Statistics and conducted by the Bureau of the Census provides in many ways the most comprehensive over-time data on consumer behavior of any such "panel" study in existence. This data base has been frequently utilized by home economists and consumption economists. However, this data and similar data collected in other countries have received only scant use by, and attention from, consumer researchers.

As Sheth (1980) points out, much existing government and private data on consumer behavior goes unanalyzed, while more data is collected; more theories are left untested while new ones are developed. Furthermore, much of this government data is collected from large, national probability samples--just the sort of data base which is generally not economically feasible for most academic research. Sheth suggests that the analysis of existing data become a priority for future consumer research efforts. The existence of the Consumer Expenditure Survey data provides one major opportunity for those interested in any number of aspects of consumer behavior to do just this.

Purpose

The purpose of this paper is to: (1) provide background information on the methodological changes in the Consumer Expenditure Survey, (2) compare and contrast the current C.E.S. with other well-known panel studies, (3) outline the unique advantages and potential drawbacks of the C.E.S. for consumer research and (4) suggest several sets of illustrative research questions for which C.E.S. data should be particularly appropriate for answering.

Background

As has been discussed in other papers in this session, the current methodology used for the current C.E.S. is markedly different from that which was used in the previous surveys done in 1950 and 1960. In those years, respondents were asked, in basically one or two long interviews, to recall all of their household expenditures throughout the previous year. There is substantial evidence that this

task was too difficult for many respondents, particularly for non-durable goods. The recall method has, even for shorter recall periods, been shown to produce seriously inaccurate reporting (Sudman and Ferber 1974).

Beginning with 1972-1974 survey, and continuing through the current survey, the diary method has been used to collect expenditures on inexpensive non-durables. The recall method is used to collect expenditure data for more expensive durable goods and regular expenses such as rents, utility bills and insurance premiums. The recall period for durables is 3 months. Diary data is collected only over a 2 week period.

BLS is now engaged in an ongoing or continuous Consumer Expenditure Survey Program. Whereas the 1950, 1960 and 1972-74 surveys were one-time surveys, the current survey collects data on at least a monthly basis. The survey's dynamic character, along with its improved data quality, allows for analyses not possible with previous surveys. For instance, analyses of the short-term impacts of major social events could not be made with the 1950 and 1960 surveys since the data collected was for a single one-year period. While such analyses--over a 15 month period were possible with the 1972-74 data, measures of expenditure changes in the years after 1961 and before 1972 and in the years after 1972 and prior to the current survey were not.

The data quality especially for non-durable goods purchases has been markedly improved (since the 1960 survey) through the use of the diary method. The data on these expenditures may be more comprehensive than any such data previously collected. As Pearl (1981) points out, the Consumer Expenditure Survey obtains the most extensive travel expenditure data ever collected.

Some Major Commonalities and Distinctions Between the C.E.S. and Commercial Panel Studies

There has been somewhat substantial use of and reference to consumer panel data in the marketing literature (e.g., Ahl 1970; Cherington 1943; Frank and Strain 1972; Massy and Frank 1965). For a review of the use of consumer panels in marketing see Sudman and Ferber (1979). Some of the same objectives illustrated in these studies can be satisfied through use of the C.E.S. data. A comparison of the C.E.S. to a major consumer panel such as Market Research Corporation of America (MRCA) national consumer panel, does however, reveal major similarities and differences. Both "panels" provide over-time data on the quantity and type of item purchased. Both panels provide data on prices paid.

The C.E.S. does not, however, provide information on the particular brand purchased or whether or not the item was purchased with a coupon or some other promotional "deal." The latter types of data are usually obtained in commercial panel studies. The C.E.S. does not obtain data on outlets shopped. However, a separate study sponsored by BLS, the Point-of-Purchase Survey, does provide a means for some types of outlet studies.

Some commercial panels also have measures of a wider variety of household characteristics to relate to expenditures--e.g., life styles, than are obtained in the C.E.S., as well as attitudinal measures regarding products for

which purchase histories are obtained. The Consumer Expenditure Survey obtains no data on attitudes, life styles or behavioral intention. Thus, while desirable, over-time analyses of the relationships between these other household or individual characteristics and behavior are not possible with existing C.E.S. data. However, as Jacoby (1978) points out, the analysis of consumption itself and its consequences for subsequent acquisition decisions deserves more attention in the consumer behavior literature.

The C.E.S. and MRCA panels differ in terms of the length of time participants remain in the panel. The maximum length of time for participation in the C.E.S. is 15 months. MRCA's panel members may, for instance, remain in the panel indefinitely. This continual replacement effectively removes the C.E.S. from categorization as a longitudinal study. Longitudinal analysis requires over-time observations to be made on the same sampling units. The C.E.S. is longitudinal for a maximum of 15 months--the five quarters for which data is collected. However, no longitudinal analysis is possible for non-durables since this data is collected for only one two-week period.

Perhaps the major difference between the C.E.S. and other major panels is the breadth of the consumption expenditures measured for each sampling unit. MRCA has a panel for grocery items and another for clothing. General Electric has a panel which is concerned with major appliances. The C.E.S. measures virtually every conceivable type of expenditure using the same panel. The existence of this almost totally comprehensive expenditure data provide the unique opportunity for assessing expenditures on certain goods and services relative to expenditures on other products. This extensive detail is necessary to allow for the continual updating of weights and market basket items used in calculating the Consumer Price Index (CPI). Within some limits to amount of detail in, and specificity of, product breakdowns researchers interested in consumer expenditures on virtually any type(s) of product(s) can obtain high quality data through use of the C.E.S.

Some commercial research firms have been amenable to releasing panel data to academic researchers a specified number of years after the data has been collected. Current panel data is however, for most academic researchers, too costly. In contrast, the data tapes sold by BLS are relatively inexpensive.

Sales and distribution audits also provide data on consumer expenditures for a variety of products. Information on expenditures across types of retail outlets also is available. However, these data offer no opportunity for analyses of differences in expenditures by various subgroups of the population. An additional drawback is the relatively high cost of current data.

Other Benefits of The Consumer Expenditure Survey Data

As mentioned above, the C.E.S. provides interested researchers with the opportunity to analyze over-time data collected from a large national probability sample. There are some methodological concerns regarding the validity and reliability of some of the data (see other papers in this session--e.g., Pearl 1981). Nevertheless, the data quality, overall, is likely to be superior (i.e., in terms of producing lower total survey error on any given item of data) to most data which has been utilized in academic research (especially those data derived from student or local household convenience samples).

The C.E.S. data is particularly well-suited to macro or group level, as opposed to micro, analyses of consumer behavior. The former approach has been classified as a major need for consumer research in the 1980's (Sheth 1980).

The sheer comprehensiveness of expenditure data present in the C.E.S. allows researchers to overcome the weaknesses in analyzing consumption of a single product and making generalizations about consumer behavior based on that single category of product. The C.E.S. data allows for an analysis of the total consumption structure of a household.

The unit of analysis--the sampling unit for the C.E.S. data, called the consumer unit, is almost always the household. The view that the household, as opposed to the individual, is the appropriate unit of analysis for consumer research has gained growing support (Ferber 1980). Only in certain circumstances (i.e., based on the financial independence of one cohabitant from another cohabitant) will a household--i.e., place of residence, contain more than a single consumer unit. BLS estimates that 95% of all households will contain a single consumer unit.

Although the C.E.S. and commercial panel data are based on self-report data as opposed to direct observation or record checks, the data deals with actual purchases--i.e., expenditures. There are no attitudinal measures taken.

Kassarjian, for one, has argued for more research into consumer behavior which relies on unobtrusive and nonattitudinal measures--(e.g., analysis of current periodicals, advertisements, etc.) insofar as they reflect the changing values and attitudes of a society. Actual expenditure data deals with the end-result or activity that an analysis of these factors intends to predict. Researchers who wish to make inferences as to what value/attitude changes are taking place can look to the current production of visible tangible symbols of a society (its art, literature, etc.). However, it also is important to analyze the actual consumption patterns of various segments of the society and society in general. There are, of course, relative disadvantages to any single approach--e.g., determining whether or not changes in art, or literature are lagging behind or preceding the value or attitude changes that help to produce changes in consumer expenditures. Furthermore, consumer expenditures are constrained by what sellers choose to offer in the marketplace. Thus, consumer behavior may be reflective not of what consumers are thinking, feeling or desiring, but rather what compromises from what is wanted or needed they are willing to make given the limits of the marketplace.

The complex and interesting questions surrounding the macro aspects of consumer behavior render any one means of assessing long term shifts in value and expenditure somewhat inadequate. Multiple means/indicators are required. Nevertheless, the comprehensive expenditure data available through the C.E.S. is one such means of assessment that has not been fully utilized by consumer researchers.

Possible Research Programs Utilizing the C.E.S. Data

The following are illustrative examples of the research questions and issues for which the use of the C.E.S. data would be most appropriate and useful.

1. Analysis of Long Term Predictions for Changes in Consumer Behavior:

How do changes in consumer expenditures compare to the long-term changes in consumer behavior predicted by various pundits and forecasters?

For instance, the Yankelovich research organization regularly tracks changes in a number of major cultural values. Based on this organization's surveys, predictions for major changes in consumer values in the U.S. are made. These changes in values will ultimately influence attitudes and purchase behavior toward a wide variety of goods and services (Kotler 1980: Loudon and Della Bitta 1979). The

Consumer Expenditure Survey data can be used as one means of testing specific propositions about changing values and consumer behavior through an analysis of changes in consumer expenditures.

2. How are consumer expenditure patterns influenced by the major changes in characteristics of households?

(a) How do consumption expenditures of married households in which both spouses work differ from those married households with wives who are not employed outside the home? This is a popular issue and source of conjecture among home economists, consumer researchers and marketers. Still, there have been few empirical studies examining the full range of implications of the working wife on household buying behavior.

One study dealing with this issue utilized data obtained from a 1967-70 Survey Research Center study of consumer finances. Holding income, education, family life cycle and other socioeconomic and demographic measures constant, the labor-force participation of wives was related to overall household consumption expenditures, and expenditures on durable goods (both as a percent of total income) (Strober 1977). Strober found that holding other factors constant, households with working wives had a significantly higher consumption expenditure to income ratio than did households without working wives. The labor-force participation of the wife, however, had no significant effect on total expenditures or durable goods (as a percent of total household income). This study tests several hypotheses developed in economics regarding the expenditures of households with working wives (see Strober 1977 for a brief overview of these hypotheses). There seems to be a great opportunity to merge the consumer behavior theory developed in sociology, marketing and psychology with these economic theories to further explore these issues. At the very least additional tests of the hypotheses developed in economics could be made. The Consumer Expenditure Survey data again provides an excellent data base for such research.

(b) How do these consumption expenditure patterns change as a function of the age of the wife/husband, number and ages of children or overall family life cycle of the household?

There have been two recent studies of the impact of family life cycle on various consumer expenditures. The first of these studies was, in fact, based on Consumer Expenditure Survey data collected by the Government of Norway (Arndt 1979). The other study was based on a local commercial survey in the U.S. (Landon and Locander 1979). Both of these studies have, however, been criticized for failing to allow for, or to hold constant, other factors (aside from family life cycle) likely to influence the expenditures under consideration--e.g., income, education and occupation (Ferber 1979). As such they provided no opportunity to assess the efficacy of family life cycle relative other household characteristics in explaining consumer expenditure.

The Consumer Expenditure Survey provides ample data for constructing various formulations of family life cycle. Those interested in conducting such research might well consider the criticisms, and suggestions for modification, of the family life cycle concept itself (Murphy and Staples 1979). In addition, the Consumer Expenditure Survey data contains measures of the household characteristics needed for the multivariate analyses required to establish the usefulness of the family life cycle concept--in whatever form, for explaining consumer behavior. The continuous nature of the survey allows for an analysis of the short-term impact (i.e., impacts on durable goods expenditures) of changes in household composition or life cycle--e.g., a new baby.

(c) Assessing the impact of other changes in household composition.

The dynamic character of the current C.E.S. allows for an analyses of the short and long-term effects of the aforementioned changes in household composition. The effects of other changes such as a loss of job or death in the family also can be assessed.

3. How do consumption expenditure patterns of Blacks, Whites and Hispanics differ? Do these expenditures differ when age, education, income and other relevant demographic characteristics are held constant or controlled for across the two groups? If so, which types of expenditures differ?

Recent research indicates that in similar occupational, income, educational age and life style categories there are few Black-White differences in consumption (Edmonds 1979). The Consumer Expenditure Survey offers an extensive data base for making these cross-sectional comparisons over time.

4. What changes in consumption (e.g., percent of income spent on the good or service) occur as income increases?

These issues have concerned economists (e.g., with respect to Engel's Law) and other researchers for a number of years (see Prais and Houthakker 1971). It should be interesting to note where these shifts have been occurring in recent years.

BLS has, in past years, calculated income sensitivity ratios. These ratios represent the percent increase in expenditure on some item (i.e., usually a broad category of items) resulting from a one percent increase in real disposable income. One drawback in the use of these ratios has been their timeliness (Reynolds and Wells 1978). However, with the switch by BLS to an ongoing C.E.S., these ratios can be kept much more current. They provide a means for marketers to calculate likely changes in consumption of their products with changes in disposable income levels. They also provide a means of assessing the effects of sheer increases in disposable income on relative increases in the consumption of various products (i.e., tests of income--related consumption hypotheses.)

5. Profiling the Heavy User:

Comparisons of heavy users of a particular category of good or service with light users are easily facilitated with the Consumer Expenditure Survey. These comparisons can be made in terms of the various household characteristics which are measured or can be derived (e.g., family life cycle) from the C.E.S. survey. Comparisons in terms of use of related goods or services across user categories also could be made. One possible research focus would be to compare the results to results of past "heavy half" studies.

6. The Growth of Services in the Economy

Services have, over the past ten years, grown as a percent of GNP. Potential research questions regarding the growth of services include: Which particular service expenditures have exhibited the greatest increase? How do these rates of increase compare across categories of households? Are these expenditure changes reflective of recent predictions for consumer shifts to the service sector of the economy? These changes in the over-time expenditures on services are best measured by the continuous survey now in progress rather than by separate surveys conducted at yearly or 5 or 10 year intervals.

7. Applications of Life Style or Consumption Style Approaches to the Study of Consumer Behavior

While the Consumer Expenditure Survey does not obtain life style data based on activity interest and opinion questions, it does allow for a means of inferring life styles from actual consumption behavior. The use of actual consumption data is one of several means of assessing life styles (Wind and Green 1974). The use of particular products, which might be considered to be part of the activity component of life styles, has been correlated with the purchase of other products of interest (see, for example, Hustad and Pessemier 1974--for a review of such studies, and Bass, Pessemier and Tigert 1969 and Reynolds and Wells 1978).

Sheth (1980) discusses the need for more research dealing essentially with a typology of consumption life styles. This research would involve an analysis of "the time dependent covariances of preselected and representative goods and services." The Consumer Expenditure Survey data is ideally suited to just such a research approach. Life styles can thus be inferred from actual consumption patterns and not merely activity interest and opinion data. Analysis of trends in life styles based on changes in consumption of various types of products would presumably be of major interest to marketers, consumer researchers interested in the overall consumption trends in the market place, and sociologists and others who wish to discover evidence for changes in values and life styles, over time.

There has been some recent research in these areas. One study analyzed the correlates and consumer behavior implications of changes in consumption style (Uusitalo 1980). The author determined a variety of consumption styles by forming eight combinations of three consumption indices. The consumption indices were based on factor scores produced in a factor analysis of consumer expenditures on 220 items. The expenditure data was derived from Consumer Expenditure Survey data collected by the Statistical Central Office of Finland. The consumption styles derived from these analyses were then related to total consumption expenditures and individual expenditures on specific categories of products.

One possible caution with respect to such analyses is in relating predictor variables derived from particular expenditures to essentially the same expenditures. A better method would be to derive the consumption style measures from one set of expenditures, and then using those measures to predict another set of expenditures.

8. Cross-Cultural Analyses of Consumer Expenditures

Already in this review of possible research programs involving the use of the C.E.S. data, three different national consumer expenditure surveys have been discussed. In fact, there are nine European countries with which cross-cultural comparisons are possible. Such studies are now more easily facilitated due to the use of much more comparable expenditure survey methods (see, Statistical Office of the European Communities 1980). One additional interesting aspect of such research is the possibility for comparisons of expenditures with Iron Curtain Countries.

9. Examining Trends in Consumption Using New Categorizations of Goods and Services

What do sports equipment, vacations, and tickets to a play have in common in terms of satisfying consumer needs? How are they representative of different types of consumer needs? What are the underlying consumption trends in the vast array of changes in consumer expenditures? Clearly, better characteristics of products (goods and services) theories--i.e., categorizations of products according to what value expression or sought need they represent are

needed to answer these types of questions. The convenience goods--shopping goods--specialty goods breakdown clearly is not sufficient for making projections in needs-based categories of expenditures, or in making inferences from expenditure data to value shifts. Work in analysis of consumption as it pertains to the acquisition of particular benefits has been done by Lancaster (1975) and Ratchford (1975).

Some trend studies of consumer expenditures published by BLS break all consumer expenditures down to expenditures on food, housing, clothing, medical care, transportation, recreation (which includes among other things expenditures on education, reading, alcoholic beverages and tobacco). There are certain to be subtle differences within each of these expenditure categories which when guided by a theory-based approach could yield new insights into consumer behavior. Furthermore, as Nicosia and Mayer (1976) point out, differences in the nature of expenditures made within a particular expenditure category may have important public policy implications. For example, the satisfaction of entertainment needs via attendance at spectator sports versus purchase of records or books will influence energy utilization, use of roads and mass transit, consumption of food and drinks away from home etc.

10. Impact of Major Social Events on Consumer Behavior

As mentioned above, the continuous collection of expenditure data allows for an assessment of the short-term impacts of major social events on consumer behavior. For instance, the impact of such events as oil embargoes and resulting gasoline shortages, the eruption of Mt. St. Helens, major new product introductions such as K-Body cars or video disc players, shortages of certain products, new laws, major economic changes (e.g., rises or falls in inflation) or political changes (e.g., the election of a new president) can be measured by the continuing survey.

Conclusion

The Consumer Expenditure Survey has provided, and continues to provide, interested consumer researchers a rich data base which can be used to satisfy a variety of research interests. There is certainly room for creative, theory-based approaches to the analysis of the C.E.S. data. Fundamental tabulations and cross-tabulations of expenditure data--of the type published by BLS and the Conference Board are some of the most important analyses performed. However, there is much room to go beyond these analyses to answer some of the more complex questions consumer researchers and public policy makers have, especially in recent years, been posing. The C.E.S. data holds out the promise of not only enabling consumer researchers to see what is happening and what is likely to happen in terms of actual consumer behavior in the market place, but also providing the insights and tests of hypotheses which will assist these researchers in determining the reasons for these behaviors.

NONRESPONSE IN CONSUMER SURVEYS

Fred Wiseman, Northeastern University

Abstract

Response rates in consumer surveys have declined in the 1970's due to a number of controllable and uncontrollable factors. This decline has been a source of concern to many professionals in government and private industry. As a consequence, consumer researchers now find their results and inferences being challenged when they are based upon survey data which are susceptible to substantial non-response bias. This paper reviews the findings of recent nonresponse research investigations and discusses their importance and implications for consumer researchers.

Introduction

During the 1970's there was a growing interest among many social scientists and statisticians within the Federal government, private industry and academia about the negative impact that certain uncontrollable, environmental factors were having on the survey research process.

Changing life styles, increased female participation in the labor force, flexible working hours and more leisure time made it increasingly difficult for a potential respondent to be contacted by an interviewer. Further, if and when contact was made, numerous other factors such as privacy related concerns, fear and suspicion of strangers, questions regarding survey legitimacy and excessive interviewing resulted in a substantial percentage of contacted respondents deciding to refuse participation.

In 1973, the American Statistical Association brought together a diverse group of social scientists and survey methodologists in order to discuss the problems of conducting present-day surveys of human populations. From the discussions that took place, a number of conclusions were reached. Among these was that "Survey research was in some difficulty, and, to an undetermined scale, that difficulty was increasing." For example, some participants noted that completion rates on general population surveys averaged 60-65% compared to 80-85% in the decade of the 1960's (The American Statistician, 1974).

What are the consequences of increased nonresponse on data quality? This is a question that cannot easily be answered in a survey because nonresponse bias depends not only on the magnitude of nonresponse, but also on the degree to which nonrespondents differ from respondents on the variables of interest. However, in discussing the effects of nonresponse, Platek (1977) points out that since the sampling variance of the estimates is inversely proportional to the response rate, estimates based on a simple random sample with 80% response rate will have a sampling variance that is 12½% higher than the variance of corresponding estimates with 90% response rate.

This paper will briefly review some of the key findings of recent studies and investigations that have focused on nonresponse and data quality related issues. In addition, it will discuss efforts that are now underway that will hopefully result in an improved understanding of the nature and extent of nonresponse in consumer surveys. Finally, implications for the academic research community will be explored.

Concerns About Nonresponse/Data Quality in Federal Agencies

As an outgrowth of the 1973 ASA conference, the National Science Foundation agreed to support a pilot study in which 36 surveys were examined in detail in order to determine the extent to which stated survey objectives were achieved (Bailar and Lanphier 1978). Of the 36 surveys, 26 were conducted by or for the Federal government and the remaining ten by state governments, academic institutions or professional associations. The major finding of this investigation was that:

Twenty-two of the 36 surveys did not meet their objectives because of technical flaws such as a low response rate, the inclusion of inferences in the final report that could not have been substantiated by the survey results, no validation of survey interviews and no data "cleaning."

With respect to response rates, Bailar and Lanphier stated that they were difficult to collect and compare as they were found to have different names and different definitions in different places and circumstances. Further, when response rates were reported, they were often inflated.

A second major investigation was recently completed for the Comptroller General of the United States upon request of three members of the U.S. House of Representatives (Comptroller General 1978). The study examined the potential for incorrect or unreliable information being generated by public opinion polls and attitude surveys sponsored or conducted by Federal agencies. The Congressmen were concerned that poor quality data from surveys were being used as the basis for making Federal management decisions that affected national programs and policies.

In carrying out the study, the General Accounting Office (GAO) identified a number of recently conducted surveys at various agencies and decided to review five in detail. Their overall conclusion was:

Although there were no indications that survey results were intentionally misused, use of the results of all five should have been limited because each contained serious technical flaws.

Numerous examples of these technical flaws were cited by the GAO in their report including those in a survey designed to provide an information base for use in a model that compared potential national carpool incentive policies. The GAO concluded that findings could not be used for national projections because of the type of sampling used and the extremely low response rate.

As a result of that study, it was recommended that Federal agencies be given more explicit guidance as to what constitutes a good attitude survey or opinion poll and that the use of surveys which contain extensive technical flaws should be discouraged.

Given the concern within the government about the widespread use of faulty surveys, it was not surprising to see that the Federal Trade Commission, in a precedent-setting case, recently ruled that Litton Industries advertisements for its microwave oven violated Federal law because the survey research data used to justify the ad claims were

defective (Marketing News 1980). Irving Roshwalb, of Audits & Surveys, Inc. was asked to testify in that case and he'll later describe in more detail the specific nature of the issues raised.

- Overall, response rates were low, with a median rate of 30% for surveys in the data base.

Concerns About Nonresponse/Data
Quality in Private Industry

In general, it appears that both users and producers of survey research in private industry have not paid as much attention to nonresponse related issues as have their counterparts within the Federal government. Among the reasons for this are (1) time pressures, (2) budget limitations, (3) client specifications, and (4) less stringent precision requirements. However, there is a growing awareness of the problem within the industry and a realization that improvements must be made in terms of research methodology in order to insure that accurate and reliable data are obtained.

During the past four years, Prof. Philip McDonald and myself have conducted a major nonresponse research investigation. This investigation carried out under the sponsorship of the Marketing Science Institute, has had the cooperation of their member firms as well as those in CASRO, the Council of American Survey Research Organizations. In 1978, 32 MSI and CASRO firms supplied data from 182 consumer telephone surveys that were conducted over a six week period. Collectively, for these surveys, there were over one million unique sample members selected to be interviewed. We found (Wiseman and McDonald 1978):

- A relatively large percentage of potential respondents/households were never contacted. The median non-contact rate was 40%.
- Of those individuals contacted, slightly more than one in four refused participation. The median refusal rate was 28%.

The analysis of the data received from these commercial companies suggested that low response rates were due more to controllable, than to uncontrollable factors. For example, in almost 40% of the surveys only one attempt was made to contact a potential respondent and rarely did a research firm make a concerted effort to convert reluctant respondents.

Potential Consequences of Nonresponse

The seriousness of low response rates depends upon the extent to which respondents differ from nonrespondents on the variables of interest within a survey. It may be that those individuals who are difficult to reach or who are unwilling to be interviewed share the same general attitudes, opinions, preferences, etc., as do individuals who are readily accessible and who are willing to be interviewed. If this be the case, then the potential consequences of a low response rate are substantially reduced.

If, however, significant differences do exist between respondents and nonrespondents then survey results, no matter how large the sample size, are likely to be of little value to decision or policy-makers.

Little is known about the characteristics of nonrespondents. However, in a number of recent studies, differences on a number of dimensions have been found to exist among those who readily respond in a survey, those who initially refused, and those hard-to-reach people who responded only after a large number of callback attempts. For example, Table 1 presents the results of four such studies in which various categories of nonrespondents were found to differ from their readily accessible and cooperative counterparts.

TABLE 1
Dimensions Upon Which Refusers and Hard to Reach Individuals Differed From Accessible and Cooperative Respondents

Study	Population	Topic of Survey	Compared to readily accessible and cooperative respondents	
			Refusers	Hard-to-Reach Individuals
Ankelberg and Day [1973]	National Survey - H-O-H conducted in 1967 by Survey Research center, University of Michigan.	Consumer finances	----	<ul style="list-style-type: none"> ● Young ● Better educated ● Higher income ● More likely to live in large cities
The Data Group, Inc. [1967]	National Survey - female H-O-H	Attitude, opinion and consumption habits	<ul style="list-style-type: none"> ● Older ● Less likely to be employed full time ● Shop less often ● Go out less often ● Less aware of new products 	<ul style="list-style-type: none"> ● Younger ● Higher income ● Socially active ● Shop more often ● Spend more on entertainment
van Westervhoven [1978]	National Survey (The Netherlands) - female H-O-H	Attitude, opinion and consumption habits	<ul style="list-style-type: none"> ● Older ● Lower social class ● Urban ● Make fewer purchases 	<ul style="list-style-type: none"> ● Working woman ● Age: 35-49 ● 1-2 person hh ● Few small children
O'Neil [1979]	General population survey of Chicago telephone households	Attitudes toward crime in Chicago and how police are handling it	<ul style="list-style-type: none"> ● Blue collar ● Service workers ● Less educated ● Lower income ● Older ● Less social participation 	

As can be seen, the results of the four studies with diverse populations show a measure of similarity with respect to the characteristics of individuals who are difficult to reach and those who are reluctant to grant an interview. However, it appears that on a number of dimensions, the characteristics of refusers are opposite those of hard-to-reach individuals. Thus, a strategy that involves a large number of callbacks without including any extra effort to convert initial refusers is one that is likely not to improve the representativeness of the sample. In addition, to completely assess the nature of nonresponse bias, we also need information on how the various response and nonresponse segments vary with respect to the key variables of interest in a survey and not just on their socioeconomic and demographic compositions.

Nonresponse Task Forces

As a result of the research that has taken place during the last few years, two Nonresponse Task Forces have been recently established involving members of MSI and CASRO.

The first Task Force, chaired by Lester Frankel (former President of the American Statistical Association) has been given the charge "to develop a uniform formula for measuring completion rates in the survey research industry for all modes of data collection -- mail, telephone and personal interview." This Task Force not only includes MSI and CASRO representatives, but also includes representatives from the Bureau of the Census, and Office of Federal Statistical Association.

It is anticipated that the Task Force will make its recommendations within the next year and, hopefully, after discussion within the survey research community, a set of standardized definitions and reporting procedures will be adopted. Such standards are long overdue.

A second Task Force is working on the development of a research design for a large scale study that will examine, in detail, the characteristics of nonrespondents and the impact that their exclusion has on survey results. At the present time we envision a national sample of 4,000 heads-of-household with up to 25 callback attempts made to locate as many hard-to-reach and "nonresponders" as possible.

Implications For Academic Researchers

The current thrust and interest in nonresponse related issues has important implications for academic researchers in three different areas: (1) teaching, (2) research, and (3) consulting.

Those in academia have a responsibility to stress, more than has been done in the past, the importance of data collection techniques and the need for quality data. We now have sophisticated sampling and experimental designs, along with methods of analysis. The element that links these two areas together is data collection and, too little attention has been given to this subject. Researchers should be concerned about low response rates and the potential impact that non-response and other forms of nonsampling errors can have on data quality. In a 1977 panel discussion sponsored by Advertising Age, leading research professionals indicated that one of the major problems facing the industry was the lack of competent research professionals (Advertising Age 1976).

In consulting activities and in testimony, as Keith Hunt emphasized in his presidential address last year to ACR members in San Francisco, it is incumbent on the research professional to stress the need and importance of sound methodological procedures especially if the results of consumer research will be used externally as well as internally. The Litton case should serve as a warning that the FTC and other government agencies will be looking very closely at claims and inferences that are made as a result of

attitude surveys and opinion polls.

Finally, in conducting our own research, attention again must be given to data quality and improved response rates even if this means working with smaller samples. Lipstein (1975) made an eloquent plea for this in his excellent article entitled, "In Defense of Small Samples." It appears now that government sponsored studies will be more closely scrutinized than they have in the past. This is also likely to be true for articles submitted to scholarly journals. For example, in the current Journal of Marketing and Journal of Marketing Research style sheet, there is the following statement: "Do not ignore the nonrespondents. They might have different characteristics than the respondents." Bob Middlestaedt and then Bob Ferber can tell you a little more about the quality of our own data reporting and implications for journal acceptance.

RESPONSE RATES AND INTERNAL VALIDITY:
SOME IMPLICATIONS FOR OUR LITERATURE

Robert Mittelstaedt, University of Nebraska, Lincoln

Introduction

One of the dangers of exposing one's students to some of the classic writings in the Philosophy of Science is that they begin to ask serious questions about the adequacy of the empirical base of our generalizations and our explanatory models. Three years ago, having read of the role of replication in the advancement of a discipline, members of the graduate seminar, which I was privileged to lead, began to consider replication in the literature of our field. The semester ended, the seminar was over, but their - and my - interest continued and led to a wider consideration of the issue and a small-scale study of the replicability of studies reported in the marketing and consumer behavior literature (Madden, Franz and Mittelstaedt 1979).

As that study progressed, several points became evident. First, many are willing to extoll the virtues of replication but, when pressed, oppose those moves which would facilitate or support studies which attempt to replicate. Second, much of this opposition seems to proceed from a distrust of the motives of would-be replicators. Third, this distrust, in turn, largely follows from a misunderstanding of the nature of replication. Many seem to believe that, necessarily, the process requires one to provide raw data to anyone who asks to see it and/or answer innumerable foolish questions from those who are too inert or inept to devise their own research projects.

It is the purpose of this paper to describe the several kinds of and purposes for replication and to relate these to the nature of the sampling process and the reporting thereof. Following that, the results of a modest scanning of a sample of ACR papers will be reported which will lead to a few conclusions and recommendations.

Types and Purposes of Replication

A useful classification of the types of replication is given by Lykken (1968) who differentiates among literal, operational and constructive varieties.

Literal replication is the exact duplication of the original study's sampling procedures, measurement techniques, experimental conditions and methods of analysis. In consumer behavior, literal replication is almost impossible, although testing for split-half reliability or the use of a holdout sample in discriminant analysis comes close to Lykken's concept. If this sort is possible at all, it seems to be the kind of replication which could be conducted only by the original study's investigator or his/her close associates.

Operational replication begins with the methodological recipe of the original study and attempts to follow it as closely as possible. For one investigator to replicate the work of another, it is obvious that it would be necessary to know a great deal about the methods of the original study. Realistically, no one expects researchers to report this kind of detail; conference papers and journal articles would become impossibly long and exceedingly dull.

Constructive replication occurs when one deliberately avoids the methodology of the first study to verify its

findings by other means, thereby enhancing the generalizability of those relationships. The researcher attempting the constructive replication of another study needs enough information about the original to determine the probability that the relationship exists, its possible strength and the general circumstances in which it is likely to be found. Thus, a description of methodology which allows meaningful interpretation of results, is sufficient to permit the constructive replicator to decide whether or not a study's findings are worth replicating, to choose another methodological recipe and to compare the findings of the replication with the original.

The purposes of replication (as suggested by Rose 1954, pp. 262-8; Selltitz, Wrightsman and Cook 1976, pp. 63-70) are to advance the knowledge base of a discipline by:

Testing Methodologies for Soundness. Obviously very tight operational replication, with prescribed variations, is needed to investigate the soundness of a methodology. Sawyer (1975) has provided some excellent examples of this type of replication in his investigations of demand artifacts.

Testing Predictions Derived From a Model, in a Context Different From That of the Original Study(ies). Since so many of our models are borrowed from disciplines which have no direct interest in consumer behavior, their predictions are most often untested in any context resembling those of interest to researchers in our field. Thus, while some findings may be well established in, say, social psychology, the first step in demonstrating their relevance to consumer behavior is to show that they hold in circumstances similar to those of the market place. To avoid total confusion if they do not work out, it is a necessity to hold methodology as constant as possible implying, again, some type of operational replication.

Testing the Generalizability of a Relationship by Extending the Findings of a Particular Study or Set of Studies to New Time, Place and Situational Contexts. Obviously, confidence in the existence of any relationship between two variables is enhanced by finding that it holds across a wide variety of circumstances. When Rogers and Shoemaker (1971) report that 203 of 275 studies have found education to be positively related to innovativeness, we accept this generalization, partly because of the sheer number of supportive findings but, more importantly, because those 203 supporting studies represent the efforts of different investigators working in various times, places, and cultural settings, using different measures of innovativeness. Extending findings involves constructive replication and, in terms of building the knowledge base of our field, may be more useful than many operational or literal replications.

Response Rates and Internal Validity

When considering the research paradigm most of us have been trained to use, and especially those with a background in the non-experimental tradition of marketing research, all questions about sampling seem to be related to the issue of external validity. In the apt phrasing of Petrinovich(1979, p. 376):

...great care is extended to obtain a representative sample of subjects from the reference population, and concern is with the reliability (and hence the standard error) of the subject population. The focus is on subject sampling, and the statistical procedures used assign individual differences between subjects to the error term against which the significance of mean differences is assessed. Great care is used to sample subjects, and pains are taken to assure that generalizations can be made to a relevant population of subjects. There is little concern, however, regarding the legitimacy of the generalizations across situations.

By contrast the central concern of constructive replication is exactly with the "legitimacy of generalizations across situations." Thus, the whole question of response rates might be thought to be nearly irrelevant to the issue of replication. Of course, knowledge of response rates would be helpful to the designer of an operational replication but, in the end, not really crucial to such an effort.

However, the informational requirements of constructive replication are essentially those needed to synthesize a study's results into the relevant literature. Thus, to the would-be constructive replicator, as to the knowledge synthesizer, the whole question of response rates - and the reporting of such rates - is important to the extent it bears on the issue of internal validity.

One obvious question arises from the likelihood that most non-response, for whatever reasons, includes the more "extreme" cases, regardless of the variable. To the extent this is true, the statistical effect of non-response is that the sample variance becomes a biased understatement of the population variance and, therefore, the calculated value of alpha understates the true probability of Type I error in any hypothesis test. While proper reporting would not lessen this problem in real terms, it would alert the interested reader to the necessity of making some subjective revision of the reported alpha level and, therefore, of effect size.

However, the issue of non-response cuts deeper. It seems unlikely that the factors which produce non-response are "random". To the extent they are interactively related with the independent variable and/or related to the dependent variables of a given study, response rate is an important internal validity issue.

To take the most obvious example, the probability of a householder being interviewed in a given study is a function of that person's allocation of time to those activities which he or she does at home. The literature of "time budgeting" supports the intuitive notion that this allocation of time between "away" and "at home" is systematically related to many other behaviors of interest to consumer researchers. However, because the nature of the probability function is partially, perhaps even substantially, controllable by callback procedures, it is essential that information about such efforts be appropriately reported, along with contact and response rates, to allow one to make an adequate interpretation of any given study.

A less obvious example involves refusals. Anyone who has done any interviewing probably has some explanations for the reason, or reasons, behind most refusals. A reasonable surmise is that many result from some sort of fear and, while we may not know the roots of those fears, it seems likely that they are systematically related to other variables of interest. But, whatever the reasons, refusals are not a random phenomenon and the reasons for their occurrence are likely to be related to other important

variables.

In summary, there are serious and substantial questions of internal validity associated with sampling procedures and, ultimately, replication is a matter of internal validity. In Kaplan's (1964, p. 128) words:

...The methodological importance of what is called repeatability is, I think, made more plain by its restatement as intersubjectivity. A scientific observation could have been made by any other observer so situated; nature plays no favorites, but exposes herself promiscuously . . . The methodological question is always limited to whether what is reported is an observation that can be used in subsequent inquiry, even if the particular observer is no longer part of the context. I ask "Do you see what I see?" to help decide whether what I see is to be explained by self-knowledge or by knowledge of the presumed object.

Reported Response Rates In A.C. R. Conference Papers

Described in this section are the results of reading of 30 A.C.R. papers randomly selected from the "Competitive Papers" sections of Volumes V, VI and VII of Advances in Consumer Research. Conference papers were chosen because they more closely reflect our collective reporting habits than do journal articles which have been revised before publication according to the standards of the journal.

Table 1 describes the general nature of the 30 selected papers. Twenty reported surveys or, at least, non-experiments. Of the remaining 10, 6 were field experiments and 4 were conducted in a classroom or laboratory. Cut along a different dimension, 15 of the studies used an ad hoc sampling procedure designed for the particular study. In 11 studies, respondents were contacted through, and because of, their membership in an extant grouping such as a panel, classroom or volunteer organization. In the remaining 4 studies, one could not tell how respondents qualified for inclusion in the study.

Regardless of the type, every paper reported a value for "n." Sometimes it was the only aspect of the sample which was reported. Most papers contained a very brief description of the pool from which the sample was drawn; these ranged from the terse (e.g., "a sample of students") to a two or three sentence description of a panel's composition.

Beyond these basic items, what one might expect depends mostly on the type of study involved. At the risk of oversimplification, but in the hope of adding some structure to what follows, it is useful to think of the potential for non-response occurring at two levels. First, there is that level or stage which contains the processes by which the sample is framed and, second, there is the level containing the processes by which usable responses are obtained from a chosen sample.

To begin with the first stage, the choice of a sample frame, in effect, defines the actual universe of which the sample may (or may not) be representative. In all studies involving an ad hoc sampling procedure, it may be presumed that some set of screening questions or interviewer instructions are used to "qualify" respondents. Of the 15 studies using ad hoc sampling procedures, one field experiment reported the use of screening variables but gave no indication of the number rejected because of them. Another field experiment reported the number of persons contacted and the number lost and described some of the

screeners used. Two of the surveys stated the qualifications for respondent participation but did not give any indication of the number of contactees lost as a result. Eleven of the 15 studies using ad hoc sampling procedures simply did not mention any conditions or actions which, in effect, defined the universe being sampled.

When sampling from extant groupings, the issue is a bit more complex. First, there are the qualifications for participation in the group itself. As noted, most of the panels were briefly described but only one paper made any serious attempt to describe the means by which the panel had been formed or maintained. It is apparent that those who have access to commercial panels believe that mentioning such a panel by name is sufficient to describe its "representativeness." In a similar fashion, those who use classroom or volunteer organizations as samples seldom feel constrained to describe the "profile" of such groupings; only one paper described the general nature of the volunteer groups from which its respondents were drawn. Second, some further qualifications may or may not be imposed within an extant grouping. Two of the classroom experiments and one survey which drew its sample from a panel described the screening devices employed and the respondent losses associated with each.

At the second stage, it is necessary to divide the studies according to the method of data collection employed and the degree of researcher control over data collection. When a study is conducted by mail, for example, there is a considerable loss of respondents between the presentation of the instrument and the recovery of usable returns while, in the case of an interviewer-conducted survey, the major potential for non-response occurs before the instrument can be presented to the respondent. Even in experiments with extant groups, or in surveys that are administered in a "group" setting, a certain amount of subject loss can be expected, although it was mentioned in only 2 of the 6 such studies examined. In all 7 mail surveys, 2 "drop-off questionnaire" surveys and 2 of the field experiments, respondents completed instruments while out of the presence of the researcher. In these instances it is difficult to sort out the various forms of non-response. However, all but one of the field experiments reported some sort of "response rate" which, in effect, aggregated all losses between the distribution of the instrument and the counting of usable responses and expressed it as a percent of the number of instruments distributed. For example, each of the 7 mail surveys

reported the number of questionnaires sent out and the number of usable returns, although none gave any indication of any follow-up procedures not did any attempt any analysis based on quickness of return.

The surveys conducted by personal or telephone interview and the two field experiments which involved the recruitment of volunteers share a somewhat different set of problems. None of these 9 studies gave any indication of the number of potential respondents contacted, none mentioned refusals, nor did any suggest that there were any less-than-complete responses to presented instruments.

Summary and Conclusions

In the end, what a given researcher does or does not do is not really as important as whether or not what was done is openly reported in enough detail to allow the interested reader to make an evaluation of a study's internal validity. By this criterion, our collective reporting habits appear, to put it generously, rather loose. From the previous section, it can be concluded that the interested reader of A.C.R. papers would find it difficult, if not impossible, to answer either of two questions about the sample of the typical study: (1) What universe was being sampled? (2) How representative is the sample of that universe?

No one expects sampling procedures to be reported in such detail as to permit operational replication. Few would claim that such was desirable. But, what should concern everyone is that sampling procedures appear to be reported in such a way as to prohibit the extension of findings through constructive replication and the useful literature synthesis that both precedes and follows such efforts.

Some cynics claim that the reporting of methodology is so casual because many wish to obscure their sloppy procedures. Others acknowledge that the problems of reporting largely follow from a lack of understanding and propose that young scholars receive better training so that, over the next 10 or 20 years, reporting habits will be improved by attrition.

What is apparent to me is that the problem of reporting standard deserves attention now. If there is to be a body of literature, in any meaningful sense of that word, some standards must be imposed. Widely diffused and understood

definitions of response rates would be a useful first step; the quality of research might not be improved as a result, but the quality of interpretation would be enhanced considerably. Until all researchers are willing to ask, in Kaplan's phrase, "Do you see what I see?" we are not going to get very far.

THE ROLE OF RESPONSE RATES IN EVALUATING MANUSCRIPTS FOR PUBLICATION

Robert Ferber, University of Illinois

The sad news I have to report is that in the manuscripts I have seen that involve surveys, a very large portion, at least half, are either rejected or sent back to the author for revision on account of inadequate attention to response rates and their effects. Let me cite some recent examples, mostly based on composites of past studies we have seen.

1. A mail survey is conducted of the patrons of a particular service to ascertain people's preferences for different attributes of this service. The response rate after one follow-up mailing is 40%. No further attempts are made to find out about the characteristics of the nonrespondents. However, the data are subjected to an elegant multivariate analysis, the results of which are used to recommend to management how their future services should be structured, and also to suggest to this, and other worlds, how all such services should be structured. Management was very happy with the recommendations; the JCR reviewers did not go into similar ecstasies.
2. A survey of the members of a consumer mail panel yields a 70% rate of response. A multivariate model is then developed to differentiate between the users and the nonusers of particular products, projecting to the population based on a finding of nonsignificance between the responders and the nonresponders to the mail questionnaire by various demographic characteristics. In this instance, two things were overlooked. First, virtually none of the demographic characteristics included in these comparisons for nonresponse bias were significant in the later analysis. Second, the mail panel by definition is already self-selected, a good estimate for that panel being that approximately 20% of those originally contacted were in the panel. Hence, the effective response rate was not 70%, but 14%.
3. A telephone survey is made of a random sample of users of a hot line assistance service provided by a state agency. No information is provided on the type of response obtained, though the later analysis proceeded to generalize on the characteristics of the users of this service.

In giving these examples, I do not necessarily mean to imply that a high response rate necessarily means a good survey, or even that special attention should be given to nonresponse in every survey. For example, if the purpose of a mail survey is to ascertain how many and what type of people are likely to be interested in a new service, the nonrespondents do not need special study, since by not replying these people have indicated they are not interested. (In a few instances, nonresponse may not indicate lack of interest, but these are so few as to be inconsequential.) The fact remains, however, that in the large majority of cases, one of the best ways how to assure rejection of a manuscript is to have a high rate of nonresponse, pay no attention to it, and then generalize to this and other populations.

Needed Information

For manuscript evaluation, what do we need to know about response rates? The answer is essentially the same as what we need to know in evaluating a particular study. First and foremost, we need to know the magnitudes of the re-

sponse rates both for the population as a whole and for key strata. If, for example, the purpose of a study is to compare certain differences in behavior between blacks and whites, it is pertinent to give the response rates for each group.

Important also is a clear definition of response rates, since without such a definition it is difficult to evaluate the significance of particular rates. Thus, a response rate could refer to the total sample list as a base, only eligible sample members, or only those who were contacted. Since the difference between these quantities can sometimes be very great, the term must be defined before it can be interpreted.

In addition to information on the size of the response rates, it is useful to have some interpretive comments from the author on the reasons why particular response rates were encountered, especially if they are very low. Such insights can be very useful for interpreting the results of the later analysis--and also indicate whether the author is cognizant of the sort of analytical problems that may be engendered by low response.

The other key item about response rates, something that is stressed everywhere but is frequently ignored, is the effect of the response rates on the results. Some people feel this is only likely to be a problem if the response rate is low, by some suitable definition, but this is not a very useful rule and can be very misleading. Even if the response rate in a mail survey is, say, as high as 80%, if the survey deals with something like people's willingness to undertake certain energy conservation programs, the chances are that the nonresponding 20% will have very different (probably much more negative) attitudes on the subject than the responding 80%. To leave out this group of nonresponders and to generalize from the 80% could lead to very biased results.

In fact, what is meant by a low response rate? Analytically, there does not seem to be any meaningful definition. In fact, most authors seem to try not to recognize that a response rate is low, and often try to minimize the size of the response rate by referring to lower response rates obtained in similar studies, or to special circumstances that mitigated against getting a better rate of response. If they do mention that the response rate is low, they tend to point out that it is still within the wide range of response rates obtained in this type of study, and is therefore acceptable--this was the exact argument used in a manuscript that was recently processed by us. Of course, by this argument it is hard to imagine what sort of response rate would be unacceptable.

In the final analysis, it is really immaterial whether a response rate is "good" or "bad". The key question is whether the response rate is such that the results of the study are likely to be affected by some sort of nonresponse bias. Clearly, so much depends on the subject of the study and the structure of the questionnaire. If willingness to undertake conservation programs is imbedded in a questionnaire covering many other topics, the effect of nonresponse on this question is likely to be much lower than if that topic is the sole subject of the questionnaire. In either event, some consideration is needed in virtually all instances of the possible effect of nonresponse on the results obtained in a survey study. One could generalize and say that such an evaluation is even more essential in the case of mail surveys, since nonresponse rates there can

be very low, but the same basic questions have to be posed in almost any type of survey.

What Response Rates Tell Us

The fact of the matter is that the treatment of response rates can tell a journal editor a great deal about the quality of a particular survey and the soundness of the data on which the analysis rests. If the author does not even report any response rates, he or she has a probability of just about zero of getting that manuscript accepted by JCR. This is true even in the case of a purposive sample, where some authors argue that since the idea was to obtain only a certain number of interviews with people having particular characteristics, and since they did so, response rates are of no consequence. (This is only true if the author could show that the nonrespondents are no different from the respondents on all relevant characteristics for that study; if that were possible, the study would be unnecessary.)

More important to editors is not only the reporting of response rates, but how the topic is handled. If the author gives short shrift to response rates in a situation where nonresponse bias is highly likely (such as a one-topic mail survey with no follow-ups), there is a strong indication that the author is not at all sophisticated in the analysis of survey data, and the manuscript will be returned. The one exception would be where the objective of the study is to illustrate some new analytical technique, and the survey data are used only for illustrative purposes. Even then, however, any sort of substantive inferences would have to be hedged on account of the possible bias due to nonresponse, and are actually best not made at all.

Personally, I find it rather curious that there seems to be little correlation between sophistication in the use of analytical techniques, such as multivariate analysis, and understanding of the problems that stem from nonresponse and other types of biases in survey data. With the increasing use of causal modeling techniques in consumer research, one would expect an increasing positive correlation in these two skills. So far, however, the correlation seems to be pretty close to zero--those who are sophisticated in survey techniques do not seem equally sophisticated in data analysis, and vice versa.

Recommendations to Authors

On the basis of these comments, let me conclude this presentation with a few suggestions on how authors of articles making use of surveys as the primary data source should deal with the subject of response rates:

1. Cite the overall response rate as well as the response rates for the subgroups.
2. Offer explanations for the reasons why the response rates are what they are, including comparison with the response rates on similar studies.
3. Discuss the possibility of nonresponse bias and indicate, hopefully with some justification, why you feel such bias is or is not present.
4. If nonresponse bias is expected, evaluate the nature of the bias as best you can. Moreover, keep this bias in mind when making generalizations about population attitudes or behavior, as well as in evaluating the significance of your findings (even though the significance will be diminished somewhat as a result).

In making these suggestions, I am not suggesting that you lengthen the manuscript appreciably. As many of you know, space is at a premium in both JCR and most other journals, and authors invariably write too much anyway. The fact remains, however, that this information can be presented very

briefly, often in footnotes, and the results will be a much more useful and informative manuscript. The result will also be a lesser probability that the manuscript will be rejected or returned for major revision (though even with this change I am afraid that the chances of any manuscript being returned at least for revision will remain quite high).

RECENT CONTROVERSY IN WASHINGTON: AN FTC CASE

Irving Roshwalb, Audits & Surveys, Inc., New York, N.Y.

Abstract

A recent FTC case provided the opportunity to review three important aspects of survey research employed in legal proceedings -- the role of confidentiality of survey responses in determining the admissibility of surveys as evidence, a definition of the independence of surveys, and the definition of survey response rates.

Introduction and Background

The "recent controversy" of the title involved the FTC's complaint that the survey findings used by a division of Litton Industries in its advertising were based on surveys which "...did not provide a reasonable basis for or prove the claims of the advertisements" (USA-FTC, p.5).

Later, the complaint goes on to say, "The Litton surveys had a very high rate of non-response. However, Litton failed to determine whether there was a bias of non-response, that is, whether the answers of non-respondents would have differed significantly from those of respondents" (USA-FTC, p.6).

This is, for those interested in the use of survey findings in legal proceedings, a very lively case. It presents several interesting aspects of the place of survey research in such proceedings. One of these is the problem of non-response and how it should be reported. Another deals with the terms under which a study should be deemed admissible in legal and/or regulatory proceedings. Finally, a third deals with the definition of an "independent" survey. The issues of survey "admissibility" and "independence" are discussed briefly before turning to the non-response problem.

Survey Admissibility

At one point in the hearings, the judge was asked to deny the admissibility of an FTC-sponsored survey on the grounds that there was no way for Litton counsel to identify the individual respondents and connect them with their questionnaires. The ruling of Judge John Mathias was quite to the point:

"...I find that the admissibility of surveys depends on their relevancy and trustworthiness and not upon whether respondents gain access to the codes identifying survey-respondents with their respective questionnaires" (USA-FTC Order, p.1).¹

This statement parallels the "Federal Rules of Evidence", which state, in part, "Attention is directed to the validity of the techniques employed rather than the relatively fruitless inquiries whether hearsay is involved" (West Publ. Co. 1977).

¹To keep the language straight, "respondent" in this context refers to those answering the FTC charges; "survey-respondent" refers to those interviewed as part of the studies.

What is of greater interest is that the order then proceeds to give the reasons for this finding, stressing the confidentiality of the relationship between a survey agency and its respondents. It is worth quoting in full:

"... Both (...survey agencies...) claim not only that they have given pledges of confidentiality to the interviewees, but that to break such confidentiality would be against the ethics of their profession and would be detrimental to the efficacy of future surveys to be conducted by themselves and others of their profession...there is some legal support for the surveyors' claims in this regard. Although there is certainly no pollster-client privilege, it is recognized that such claims of confidentiality cannot be lightly brushed aside. Where they can be recognized without depriving a litigant of discovery adequate to fairly meet his opponent's case, due deference should be given to legitimate claims of confidentiality" (USA-FTC, pp.6-7).

The concluding argument was:

"Since we are so dependent on surveys for much of the data upon which daily decisions are made, every attempt should be made to protect their accuracy. Yet the pollsters depend, to a great extent, on assurances of confidentiality to promote the efficacy of their product. If the survey-respondents believe they are going to be routinely re-interviewed and cross-examined in connection with any poll in which they participate, they will either refuse to participate or be guarded in their answers. In either event the survey method of gathering information is impaired. If enough people become so disenchanted with surveys that they refuse to participate, the ability to obtain a meaningful universe is seriously affected. If their answers are not free and open, the results of the poll are severely twisted" (USA-FTC, p.8).

Survey Independence

A second charge levelled against the advertising was that some of the ads carried the misleading notation that the surveys were independently conducted. The studies were actually designed by Litton and then turned over to an outside agency to execute the field work and prepare the tabulations. The judge's comments are again worth quoting:

"In either case (whether or not the ad carried the 'independent' notation) I find that the reader was not likely to believe that the Litton surveys were totally independent. It is difficult to perceive how any reader of the advertisements in question could possibly believe that the surveys were conceived, designed and conducted without any input by Litton, in view of their narrow focus. Further, the contact part of the surveys -- which might be thought of as the 'conduct' of the surveys -- was, in fact, conducted independently by (... the survey agency ...)" (USA-FTC, p.6).

This represents a judicial attempt to deal with the concept of an "independent survey" by pointing out that independence is not an absolute judgment but one that must be dealt with on some relative scale and reasonably.

Non-Response

The discussion of non-response in the affected studies was part of a much broader discussion of whether the studies were conducted according to the standards of the industry. The use of surveys in legal proceedings is generally governed by this concern. The U.S. Judicial Conference has recommended that the party offering the survey in evidence has the burden of establishing "...that the survey was conducted in accordance with accepted principles of survey research" (McCarthy 1973, p.508). One of the areas on which evidence would be required is that, "the sample, the questionnaire, and the interviewing were in accordance with generally accepted standards of objective procedure and statistics in the field of such surveys" (McCarthy 1973, p.509). It would appear, however, that defining "generally accepted standards" or "accepted principles" of survey research can be a difficult task.

Before turning to the discussion of the non-response rates in the studies directly involved in this case, a brief description of the two would be useful. One called for interviewing technicians working for independent companies that service consumer microwave ovens; the other called for interviewing technicians working for independent firms that specialize in servicing commercial microwave ovens. Lists of the service agencies were provided by Litton Industries to the survey agency that conducted the field work. The survey agency's role in the study was to execute the field assignment by telephone interview and to provide tabulations of the findings.

In the "Statement of Issues" section of the complaint filed by the FTC, the following charge was made:

- "II. The surveys do not provide a reasonable basis for or prove the claims of the advertisements.
- 2. The Litton surveys suffer from basic deficiencies in survey execution.
 - B. The Litton surveys had a very high rate of non-response. However, Litton failed to determine whether there was a bias of non-response, that is, whether the answers of non-respondents would have differed significantly from those of respondents" (USA-FTC, p.6).

The basis for this charge was obtained from the report summaries prepared by Litton Industries. In one instance, the report stated that the response rate for the Consumer Microwave Oven Technician Survey was approximately 47% (234 divided by 500) of the sample. In the second survey, the finding was that among commercial microwave oven technicians the response rate was 42.2% (211 out of 500).

The available data on sample disposition for the two surveys are contained in the following table. The first column of data refers to the Consumer Microwave Oven Technician Study while the second refers to the Commercial Microwave Oven Technician Study.

	CONSUMER MICROWAVE OVEN TECHNICIANS	COMMERCIAL MICROWAVE OVEN TECHNICIANS
Total Names Called	500	500
Not Qualified	80	95
Refusals	15	25
Could Not Be Reached	171	139
Disconnected, Out Of Business	--	30
Completed Interviews	234	211

It is clear from a review of this table and from the charges made by the FTC that the calculation of the response rate contained in the charges was more like that of a "hit rate", as much a measure of the quality of the list, perhaps, as of the quality of the effort expended to complete the interviews.

There are at least two entries in the table that should not be ignored in the calculation of response rates. The first is the listing of 'not qualified' persons. As far as evaluating the effort put into completing the interviewing assignment, these 'not qualified' respondents represent successful conclusions of interview attempts. That is so, at least from the point of view of the interviewer. If we consider these as successful attempts in the Consumer Technicians Survey, then the calculation of the response rate for this group, R(C1), is

$$R(C1) = (234+80)/500 = 314/500 = 62.8\%$$

Before we attempt a similar calculation for the commercial technicians, we have to consider what to do with the 30 telephone numbers which were found to be 'disconnected, out of business'. These 30 numbers are not part of the universe. Eliminating them from the base yields a response rate for the commercial technicians, R(CM1), of

$$R(CM1) = (211+95)/(500-30) = 306/470 = 65.1\%$$

A second approach is to measure response only among those who qualify. The rationale here is, of course, that it is only those who qualify who are the object of the research and only a measure of success among this group is reasonable and appropriate. Using this definition of non-response, a second response rate among the consumer technicians, R(C2), may be calculated --

$$R(C2) = 234/(234+15+171) = 234/420 = 55.7\%$$

The comparable calculation among the commercial technicians, R(CM2), is

$$R(CM2) = 211/(211+25+139) = 211/375 = 56.3\%$$

A third definition of response rate would now argue that the 139 consumer technician telephone numbers that were classified as 'nonreachable' and the 171 commercial technicians who 'could not be reached' should not all be judged as non-respondents. Some portion of them, could they be reached, would end up as unqualified. One estimate of how many should be so classified is to take the ratio of non-qualified among those that were reached and then apply this ratio to those who could not be reached. First, among consumer technicians:

The proportion who are estimated to be unqualified among the 171 who could not be reached is

$$80/(80+15+234) = 80/329 = 24.3\%$$

Therefore, the estimated number of the 171 who could not be reached who should be counted as non-respondents is $(1.000-.243)171 = (.757)(171) = 129$. The calculation of the response rate among consumer technicians, $R(C3)$, then becomes

$$R(C3) = (234+80)/(234+80+15+129) = 314/458 = 68.6\%$$

Among the commercial technicians, in a similar manner, the 139 who could not be reached are reduced to an estimated 99 non-respondents. The calculation of the non-response rates, incorporating this estimate is

$$R(CM3) = 211+95/(211+95+25+123) = 305/451 = 67.6\%$$

The following table summarizes these calculations.

	CONSUMER MICROWAVE OVEN TECHNICIANS	COMMERCIAL MICROWAVE OVEN TECHNICIANS
Hit Rate	46.8%	42.2%
R 1 (RC1 Or RCM1)	62.8	65.1
R 2 (RC2 Or RCM2)	55.7	56.3
R 3 (RC3 Or RCM3)	68.6	67.6

Clearly, the lowest value, that corresponding to the 'hit rate', is the least appropriate measure of response rate. In this study, either R1 or R3 is more appropriate. In both of these instances the number of respondents who are contacted and who prove to be unqualified for the purposes of the study are given fair representation in the calculation of the response rate. R1, the estimate that counts as successful interviews those contacts that establish the respondent as 'not qualified', is probably the better of the two, since it involves fewer assumptions. R2 simply assumes that all who are not reached are non-respondents, even though some of them would -- if ultimately contacted -- count among those who qualify.

The need to find a qualified respondent via some form of preliminary screening doesn't appear in all telephone surveys. In many studies, any adult member of the family is eligible for interview. As the screening procedure becomes finer, the incidence of unqualified (i.e., ineligible) respondents increases, and the problem of coping with them in the calculation of non-response becomes more acute.

Setting Standards

One of the difficulties facing an expert witness in a case such as this is to be able to testify on industry standards. Wiseman and MacDonald comment in their study of response rates that "there is a lack of agreement among industry leaders regarding terminology and reporting procedures" (1978). The exercise we have gone through is a reasonable display of the variety of response rate calculations that are available and all are based on reasonable definitions of what it is we are trying to measure. In many instances, the major problem is whether response rates are reported at all, and, if reported, whether they are clearly defined.

There is one more example of response rate reporting that should be considered. Suppose the interviewing assignment requires that a given number of interviews

be completed in each of several strata. Suppose further that the response rate varies among strata. In a simple example, the following table summarizes response rates and the required initial sample sizes needed to achieve the fixed number of completed interviews (in this case 10) in each stratum. Assume that the strata sizes are equal.

STRATUM I	RESPONSE RATE = R(I)	INITIAL SAMPLE = N(I)	COMPLETED INTERVIEWS
1	.80	12.5	10
2	.50	20.0	10
3	.20	50.0	10
4	.10	100.0	10
TOTAL		182.5	40

The simplest reading is that the response rate for this survey is $40/182.5 = 21.9\%$. If the assignment were stated a bit differently - as, for example, to estimate the response rate in the universe from which the sample was drawn, the solution would be to assign equal numbers of telephone numbers to call in each stratum, observe the response rates in each, and then construct the appropriate estimate of the universe parameter, as in the following table.

STRATUM I	R(I)	NO. OF CALLS	COMPLETED INTERVIEWS
1	.80	25	20
2	.50	25	12.5
3	.20	25	5.0
4	.10	25	2.5
TOTAL			40.0

The response rate calculation for this set of data is $40/100 = 40.0\%$. In fact, the first procedure produces the harmonic mean of the strata response rates, while the latter calculation yields the arithmetic mean of the strata response rates. The harmonic mean is generally less than the arithmetic mean and would always produce an underestimate of the response rate.

This example bares another source of confusion in the calculation of response rates. Is the purpose of the calculation to come up with a descriptive, mechanical exercise to run the observed data through, or is the purpose to estimate the response rates in the universe from which the sample data have been drawn? The first is characterized by a (perhaps, apocryphal) researcher's comment made in the wake of the 1948 election poll experience that "we have no non-response problem. If we promise 100 interviews, we keep on going until we have 100 interviews." That response rates are governed by some probability mechanism has long been recognized, particularly in procedures proposed by Hartley and Politz and Simmons to weight for not-at-homes by the inverse of the probability of finding respondents at home (Hartley 1946, Politz & Simmons, 1949).

In this simple example, which calls for a fixed number of interviews per stratum where response rates may vary among strata, the mechanical calculation of response rates results in an underestimate of the response rate for the universe of the study. However, the simple arithmetic mean of the strata response rates yields an unbiased estimate of the universe response rate. So, not only must the elements of the response rate be properly designated, but the estimation procedure itself must be properly selected.

Conclusion

A number of things are quite clear as one considers the experience in this FTC case. This is an example of the ever-growing use of survey data by the parties to legal proceedings. As survey evidence finds wider usage in such matters as trademark cases, advertising substantiation and the support of product claims, the reviews of these documents can be expected to become more critical.

Creating and adhering to standards of survey research are going to become increasingly important to the users of survey research and, therefore, to the practitioners of the research art. And I use the word 'art' advisedly. It was not without careful thought that Stanley Payne named his book, "The Art Of Asking Questions" (1951).

The difficulty in setting standards for response rates is the temptation to be dogmatic, that is, to establish by fiat that response rates below some arbitrary level are inadequate or unacceptable. That is the easy way out. The FTC charge in this case states explicitly what concerns us when we discuss response rates. To repeat the relevant sentences from the charge, "The Litton surveys had a very high rate of non-response. (Forget for the moment that the calculation actually used was inappropriate. The next sentence is what counts.) However, Litton failed to determine whether there was a bias of non-response, that is, whether the answers of the non-respondents would have differed significantly from those of respondents" (USA-FTC, p.6).

Of course, that's where the answer to the problem lies, regardless of the rate of non-response. In most surveys, while this solution is implicitly recognized, it rarely is investigated thoroughly. For one thing, the nature of the non-response beast is that it doesn't make itself readily available for measurement. In any case, time and budget constraints usually preclude much effort in this direction. But there are other things that can and should be done. The first of these is to report the non-response rate, along with a precise definition of how it was calculated. The second is to state what the effect of the non-response could be, given some reasonable assumptions about the range of possible differences between respondents and non-respondents. One such solution is contained in

the nomogram reproduced below (Roshwalb 1970, p.17).

BIASES DUE TO NON-RESPONSE IN SURVEYS Binomial Variate

$$\text{LOWER LIMIT: } P_L = RP$$

$$\text{UPPER LIMIT: } P_U = RP + (1-R) \\ = P_L + (1-R)$$

For a stated response rate and the observed binomial proportion in the respondent sample, the nomogram yields directly the estimate of the lower limit of the total sample (i.e., respondents plus non-respondents) estimate if the binomial estimate for the non-respondents is taken as 0.00. It also indicates the value for the total sample if the value among the non-respondents is taken as 1.0. The possible effect of non-response on the estimate based on the total sample is thus available under very extreme conditions. With more information about the universe and subject matter under study it is possible to place more reasonable limits on the values for the non-respondents and thus obtain more reasonable estimates for the total sample.

LACK OF AGREEMENT ON THE STANDARDIZATION
OF RESPONSE RATE TERMINOLOGY IN THE SURVEY RESEARCH INDUSTRY

Joy Williams-Jones, Marketing Science Institute

Abstract

A survey of commercial research suppliers and users revealed widespread inconsistency in definition and calculation of four commonly used response rate terms. This lack of standardization may be a function of lack of formalized instruction at the academic level, and/or the fact that many response rate terms can be used for distinctly different purposes. This paper reviews results of that survey, illustrating the wide range of variation in terminology definitions; and stresses, in light of recent developments, the need for standardization of terminology across all survey research practitioners.

Introduction

Fred Wiseman earlier reported on the combined results of 182 consumer surveys shared with us by the member companies of the Marketing Science Institute (MSI) and Council of American Survey Research Organizations (CASRO) which encompassed over one million interview attempts. The main purpose of the synthesization of those results was to determine current response rates in U.S. survey research, in an effort to either corroborate or dispel the suspicions that readily reachable and cooperative respondents were becoming more and more difficult to contact.

In Wiseman's and McDonald's (1978) efforts to compare response rate data from one survey to the next, however, they encountered two problems: (1) varying terminology used to describe survey outcome "rates"; and (2) lack of comparable calculation methods used to develop these rates.

A Steering Committee composed of eight MSI member company representatives suggested surveying MSI and CASRO members in order to determine current practice in the research industry regarding the use and calculation of selected response measures used. This paper will report some of the results compiled from that survey.

Procedure

A short questionnaire was developed which asked respondents (field directors and appropriate marketing research personnel who were involved in the computation or use of response rates) to indicate:

- the relative frequency with which the following four response terms were calculated in attempting to describe the outcome of particular consumer data collection efforts;
 - Response rate
 - Completion rate
 - Refusal rate
 - Contact rate
- and next, using the results of three actual telephone survey outcomes as data sets, they were asked how they would calculate the four rates, for each survey.

The data sets included three types of sampling: (1) telephone directory, (2) random digit dialing, and (3) pre-determined respondent lists (Exhibits 1-3):

Exhibit 1

Source of Sample: Telephone Directory

Category	Frequency
Disconnected/non-working number	426
Household refusal by someone other than designated respondent	153
No answer, busy signal, not at home	1757
Interviewer reject - language barrier	150
Interviewer reject - other	37
Respondent refusal	711
Ineligible respondent	74
Completed interviews	<u>501</u>
Total	4175

Exhibit 2

Source of Sample: Random Digit Dialing

Category	Frequency
Disconnected/non working number	702
Business/non-household number	237
No answer, busy signal, not at home	1467
Interviewer reject - language barrier	15
Interviewer reject - other	8
Respondent refusal	189
Ineligible respondent	531
Termination by respondent	1
Completed interviews	<u>99</u>
Total	3249

Exhibit 3

Source of Sample: List

Category	Frequency
No phone number available for designated respondent	175
No answer, busy, not at home	13
Interviewer reject - language barrier	10
Interviewer reject - other	4
Respondent refusal	169
Ineligible respondent	10
Over quota	8
Termination by respondent	5
Completed interviews	<u>211</u>
Total	605

Results: Frequency of Terminology Usage

In total, 55 professional field directors (on the "supplier" side) and marketing research personnel (on the "user" side) responded to our questionnaire. Table 1 illustrates that completion rate is the term most commonly calculated by these researchers with 40% of the sample indicating "always"

using that figure. Contact, refusal, and response rates were not as frequently used.

Table 1

Reported Frequency of Calculation

Rate	Frequency of Calculation						
	Always 1	2	3	4	5	6	Never 7
Response	16%	22%	4%	9%	7%	13%	13%
Completion	40	29	7	2	0	9	4
Refusal	22	25	15	5	4	13	7
Contact	24	13	11	11	2	18	13

(N = 55)

It is not surprising that "completion rate" was the term most commonly used, due to the standard practice of cost bidding based on estimates of eligible respondent incidence in the population.

When a survey research supplier is requested to "bid" on a proposed project, the client is commonly asked to provide an incidence estimate for his required sample. For example, if one wished to conduct a telephone survey of 200 female heads-of-household who are regular users of a product category they might refer to TGI (Target Group Index) or other syndicated sources, to learn that 40% of females between the ages of 21 and 65, are regular users of that category. Assuming females compose about one-half the population, the incidence would be estimated at .4 x .5 or 20%. The research supplier can then assume that 2 out of every 10 contacts made should yield an eligible respondent. Based on this estimate, the research firm can then determine the number of interviewer hours that should be required to produce 200 completed interviews. (It should be noted that length of interview, sensitivity of the topic area, and "day-parts" in which the interviewing is conducted are additional factors which can be expected to affect ultimate response rates.)

Upon completion of the interviewing, the research supplier will commonly base the final study cost on the actual number of staff hours required to complete the field portion of the survey. If time estimates based on the assumed incidence figures are substantially "off," the actual incidence encountered during the field work is often used to proportionately increase or decrease field work charges.

While "completion rates" are useful in costing and planning research surveys, the common usage of this rate does not necessarily indicate that commercial researchers are utilizing that calculation as an aid to assessing data quality.

Results: Rate Calculations

Among those respondents attempting the 12 calculations we requested (Ns ranged from 37 to 50 out of 55 possible), we found substantial variability in the interpretation of the rates. Table 2 indicates the minimum and maximum reported rates for each data set.

Using the telephone directory sample data set as an example, a brief discussion of each rate illustrates the broad variation in definition, calculation and potential use revealed in the survey.

Completion Rate

Two basic interpretations, with vastly different meanings, were found for the most often calculated "completion rate"

Table 2

Summary Statistics

	Minimum	Median	Maximum	Range	N
Response Rate					
Telephone directory	12%	30%	90%	78	40
Random digit	3	20	97	94	39
List	35	54	97	62	37
Completion Rate					
Telephone directory	12	25	61	49	50
Random digit	3	12	34	31	47
List	35	51	96	61	46
Refusal Rate					
Telephone directory	17	47	65	48	49
Random digit	6	23	68	63	48
List	28	42	47	19	47
Contact Rate					
Telephone directory	23	48	53	31	48
Random digit	10	26	55	45	46
List	39	69	97	58	45

(Table 3). These were: (1) the percentage of completed interviews out of all respondents/households selected and (2) the percentage of completed interviews out of all respondents/households contacted. The latter completion rate will always have a value greater than or equal to the former rate.

A key issue with respect to the denominator of the term is whether or not it should include all potential respondents/households contacted or all originally selected.

As can be seen in Table 2, while completion rate is the most commonly used term among our sample, 13 different definitions were obtained from the 50 respondents reporting their calculation methods. Based on the specific definition used, this rate could be set anywhere from a minimum of 12% to a maximum of 61%. This range of variability may in part be due to differences in the purposes for which individual researchers calculate this rate (to be discussed later).

Response Rate

The greatest amount of confusion and uncertainty existed for "response rate," with 29 different definitions specified out of the 40 responses obtained (Table 4). Fifteen respondents did not attempt this computation, either because they never compute its value or because they were not sure how it should be done. According to our professional practitioners' calculations, the telephone directory survey achieved a response rate "somewhere" between 12% and 90%. The definitions suggested most frequently occurred only three times.

Definition 1 suggests that, for many researchers, this term measures the extent to which selected respondents/households were accounted for (i.e., were contacted and could be classified into any category at all). This interpretation differs dramatically from the traditional meaning of the term and its subsequent use as a measure of data reliability.

The second definition differs from the first only by eliminating household refusals from the numerator, suggesting that the proponents of this formula feel that the intended respondent must be reached by the interviewer if he is to be counted as a response -- even if he later refuses, terminates the interview, or is found to be ineligible.

The third method of calculation seems to be more appropriate as a "completion rate" than a "response rate."

Table 3

Completion Rate Calculations for Telephone Directory Sample

		Computed Value	No. Using	Total No.
Most Frequency Used Definitions				
1.	$\frac{\text{Completed Interviews}}{\text{All}}$	= 12%	13	50
2.	$\frac{\text{Completed Interviews}}{\text{HH Refusals + Rejects + Refusals + Ineligibles + Terminations + Completed Interviews}}$	= 25%	11	
3.	$\frac{\text{Completed Interviews}}{\text{Rejects + Refusals + Ineligibles + Terminations + Completed Interviews}}$	= 27%	7	
(Number of Different Definitions Reported = 13)				

Minimum and Maximum Reported Definitions

$\frac{\text{Completed Interviews}}{\text{All}}$	= 12%
$\frac{\text{Completed Interviews + Terminations}}{\text{Completed Interviews + Terminations + Ineligibles}}$	= 61%

Table 4

Response Rate Calculations for Telephone Directory Sample

		Computed Value	No. Using	Total No.
Most Frequency Used Definitions				
1.	$\frac{\text{HH Refusals + Rejects + Refusals + Ineligible + Terminations + Completed Interviews}}{\text{All}}$	= 48%	3	40
2.	$\frac{\text{Rejects + Refusals + Ineligibles + Terminations + Completed Interviews}}{\text{All}}$	= 44%	3	
3.	$\frac{\text{Completed Interviews}}{\text{All}}$	= 12%	3	
(Number of different definitions reported = 29)				

Minimum and Maximum Reported Definitions

$\frac{\text{Completed Interviews}}{\text{All}}$	= 12%
$\frac{\text{Refusals + Ineligibles + Terminations + Completed Interviews}}{\text{Rejects + Refusals + Ineligibles + Terminations + Completed Interviews}}$	= 90%

Looking at the difference between the definitions which produced the minimum and maximum calculations, it is obvious that researchers are confused regarding the appropriate populations to consider as the "universe" and the "responses." The definition yielding a 90% response rate, could be interpreted to mean response rate is the proportion of all respondents who interacted with the interviewer in any way that were not rejected by the interviewer as inappropriate (i.e., "We count everyone we talked to as a response except for those we were responsible for eliminating").

Contact Rate

The greatest amount of consistency existed for "contact rate," with 38 out of 49 respondents calculating rates within a range of 11 points (44% to 53%, Table 5). It's rather ironic in this discussion of precise rate calculations to consider an 11-point spread as an example of consistency, but when we realize just how great the variation is in the existing definitions of terminology, 11 points begin to sound reasonably small.

It is interesting to note that the two most frequently specified definitions for contact rate were identical to those specified for response rate (definitions 1 & 2 in Tables 4 and 5).

To simply percentage the number of refusals on all attempts -- the formula yielding the lowest rate (17%) also seems a bit unrealistic. How could non-working numbers, or not-at-homes be considered possible refusers?

Table 5

Contact Rate Calculations for Telephone Directory Sample

		Computed Value	No. Using	Total No.
Most Frequency Used Definitions				
1.	$\frac{\text{HH Refusals} + \text{Rejects} + \text{Refusals} + \text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}{\text{All}}$	= 48%	20	49
2.	$\frac{\text{Rejects} + \text{Refusals} + \text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}{\text{All}}$	= 44%	11	
3.	$\frac{\text{HH Refusals} + \text{Rejects} + \text{Refusals} + \text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}{\text{All} - (\text{Disconnected/non-working})}$	= 53%	7	

(Number of different definitions reported = 12)

Minimum and Maximum Reported Definitions

$\frac{\text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}{\text{All}}$	= 23%
$\frac{\text{HH Refusals} + \text{Rejects} + \text{Refusals} + \text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}{\text{All} - (\text{Disconnected/non-working})}$	= 15%

Definition 1 assumes that if a household is reached at all, it is considered a contact. The second limits this a little further, by requiring the specified respondent to have interacted with the interviewer.

Both of these definitions essentially imply that contacts represent the sheer proportion of households or respondents reached, out of the number of all attempts made.

The third definition does not include non-working numbers in its denominator (i.e., as a counted "attempt") thus raising the contact rate proportionately.

The method of calculating which produced the lowest (23%) rate, does not inherently seem to be well thought out. If respondents who terminate the interview are included in the numerator, why aren't refusals? Similarly, if ineligibles are included, why not those rejected by the interviewer?

Refusal Rate

Most researchers agreed that once a household contact is made, any way in which cooperation is refused or terminated (by the specified respondent or another household member) would be defined as a refusal (in the numerator, Table 6).

The denominator definition (i.e., the universe on which to percentage the refusal rate), however, accounted for most of the variation in responses with 23 different definitions supplied by 49 respondents.

It would seem rational to assume that only those eligible for inclusion in the study would be asked to participate and thus, would be the only ones able to "refuse." Definitions 1 and 2 (Table 6), however, both include ineligible respondents in the denominator. And definition 1 also leaves in interviewer "rejects."

Overall, it seems that the 65% rate makes the most sense: of those who could have been interviewed (i.e., eligible, reached, and not rejected) what proportion refused to complete or participate in the interview. However, this definition did not receive many supporters among the sample.

Conclusions About Definitions

Based on even this relatively small sample of those involved in survey research on a day-to-day basis we can draw the following conclusions:

- There is little or no consistency among either users or suppliers of survey research (within or across organizations) as to how various response and non-response terms are or should be defined.
- The traditional meaning of response rate appears to have been lost and, as a result, the term can no longer be considered as an indicator of data quality.
- The most commonly used "completion rate," when defined as "the percentage of completed interviews obtained from the total number of contacts" is of some value. It is most useful for determining the number of attempts that will be required for future surveys with the same respondent requirements as an aid for planning, scheduling and budgeting. However, unless there are no eligibility requirements posed in a survey, completion rate cannot be considered an indicator of data quality.
- New measures are needed (or old terms should be redefined) which will enable data users to assess the representativeness of their samples and the reliability of the obtained results.

Table 6

Refusal Rate Calculations for Telephone Directory Sample

		Computed Value	No. Using	Total No.
Most Frequency Used Definitions				
1.	$\frac{\text{Household Refusals} + \text{Refusals} + \text{Terminations}}{\text{HH Refusals} + \text{Rejects} + \text{Refusals} + \text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}$	= 47%	11	49
2.	$\frac{\text{Household Refusals} + \text{Refusals} + \text{Terminations}}{\text{Household Refusals} + \text{Refusals} + \text{Ineligibles} + \text{Terminations} + \text{Completed Interviews}}$	= 52%	4	

Minimum and Maximum Reported Definitions

	$\frac{\text{Refusals}}{\text{All}}$	= 17%
	$\frac{\text{Household Refusals} + \text{Refusals} + \text{Terminations}}{\text{Household Refusals} + \text{Refusals} + \text{Terminations} + \text{Completed Interviews}}$	= 65%

Sources of Confusion

In subsequent discussion of these findings with MSI and CASRO researchers we began to wonder how the problem of different interpretations materialized. First of all, none could recall the definitions of these terms being formally taught in statistics or research courses. The general experience was learning to use the definitions accepted within the companies one had worked for, or with, as a user or supplier.

Secondly, it was noted that one of the major sources of definition discrepancy was that terms such as "response, contact, completion and refusal rates" can be used for two distinctly different purposes: (1) to assess the reliability of the data obtained, and (2) to assess the quality of the data collection effort of the research supplier. Consider the following example:

A research company is asked to conduct interviews with 100 individuals whose names were obtained from a warranty card list. This list turns out to be of poor quality in that for 30 names, no phone numbers or addresses are available. With the remaining 70 names, the research supplier completes 60 usable interviews.

What response rate should be reported: 83% (60/70) or 60% (60/100)? If we are trying to assess the quality of the data collection effort, then clearly the higher rate is more relevant. If we are concerned with reliability, then the lower figure is more appropriate indicating the larger proportion of respondents who were unaccounted for. It is here that dilemma exists.

Implications for Future Survey Research

So far this discussion has centered around the issue that researchers do not agree on standard definitions for response rate terminology. Some might be inclined to conclude, "So what? As long as we know how we calculated our rates and can tell how we did it, then we can each call that percentage by any name we choose." Actually, that "so what" attitude could be supported; if all researchers agree to report their calculations, and if we as researchers were the exclusive users of the terms. That, however, is not the case on either count.

Government agencies, in an effort to improve the reliability of their survey data, which is often used as bases for policy information and program development, have increasingly begun to require researchers to guarantee a minimum response rate. In a recent national probability sample survey MSI conducted for the U.S. Department of Agriculture, we were asked to guarantee an 85% response rate. Other of MSI member companies are also reporting requirements. The Litton case illustrates that the FTC, and, we must assume, other agencies are increasing scrutiny of research already completed and using as a basis for some of their judgements the "adequacy" of the achieved response rate.

This raises the obvious question: How can a researcher guarantee to achieve a specific "rate" that can be defined (at least in the case of 39 of our researchers, Table 2), to range anywhere from 3% to 97% for the same data base?

In addition, do we really know what an acceptable response rate should be (i.e., is 85% really better than 80% in terms of the reliability of the data obtained)? The requirement that individuals and commercial researchers who use survey results in testimony, advertising claim substantiation, rate change hearings, grant research, etc., will be held responsible to meet an as yet undefined and possibly unrealistic criterion, is unsettling.

In addition, arbitrary response rate requirements can force the user of surveys into increased time and financial expenditures, which may be unnecessary for certain categories (product usage, attitudinal studies, etc.) in which non-response bias may not be a serious problem. Without the results of a definitive study to determine what topics may be more, or less, susceptible to such errors, research users leave themselves open to potentially increasing outside control of survey efforts.

Toward Resolution of the Issues

As Fred reported earlier, MSI and CASRO have recently joined forces along with representatives from the Bureau of the Census, Office of Federal Statistical Policy and Standards, Advertising Research Foundation, and the American Statistical Association, in coordinating work in response rate terminology standardization and designing a large scale national study to investigate the impact of nonresponse on the quality of data collected in surveys.

The academic community too, should play a supporting role in helping to resolve the issues at hand. Once standardized definitions have been established, it is incumbent on the academic researchers and educators to adopt these definitions, report the rates in all published research, and disseminate this terminology to future researchers currently in the universities.

INVESTIGATING "INCOME REFUSALS" IN A
TELEPHONE SURVEY BY MEANS OF LOGIT ANALYSIS

Robert A. Peterson, University of Texas at Austin
Robert P. Leone, University of Texas at Austin
Mohammad H. Sabertehrani, University of Texas at Austin

Abstract

A logit analysis was employed to investigate the relationship between refusal to answer an income question and four demographic variables. Data were drawn from a telephone survey of 6178 adult consumers regarding their financial attitudes and behavior. All four demographic variables were significantly related to refusal to respond; the primary reason given for refusal related to "invasion of privacy."

Introduction

Associated with every empirical survey is a certain amount of "error." This error can be conceptually decomposed into sampling error and nonsampling error. Sampling error is a function of data quantity--the greater the quantity of survey data, the smaller the magnitude of sampling error. Nonsampling error, on the other hand, relates to the quality of survey data, how "good" or "meaningful" the data are with regard to various criteria such as validity, reliability, and generalizability.

Traditionally most research on survey error has focused upon sampling error, perhaps due in part to reasons of analytical ease. This is in spite of the fact that non-sampling error (data quality) is likely to be more directly associated with the quality of inferences derived from the data. Recently, however, there has been an increasing interest in, and research relating to, the assessment and impact of data quality. This research has not been limited to marketing, but pervades all the behavioral sciences (see for instance, Bailar and Lanphier (1978) for several data quality issues currently being addressed).

A major nonsampling error is nonresponse or refusal to cooperate. Nonresponse may be complete, as when a sampled individual refuses to participate at all in a survey. Or, nonresponse may be partial, as when a study individual refuses to answer a specific question. This type of refusal is commonly termed an item nonresponse and is an "error of omission". It most frequently occurs for questions relating to sensitive issues such as personal hygiene or moral behavior. Item nonresponse is particularly acute in telephone interviews. This is because study individuals are neither offered the anonymity of a mail interview, nor do they experience the social pressure to answer of a personal interview.

The present research is concerned with investigating item nonresponse. While there has been voluminous research conducted on refusal to participate or cooperate in a survey per se, especially in the context of mail interviews, relatively little research has been conducted on individual item nonresponse. Still, what limited research does exist suggests that item nonresponse can significantly influence data quality in several ways (see Ferber 1966, Craig and McCann 1978, Wiseman and McDonald 1979).

Specifically, the present research consists of an investigation of respondent characteristics relating to refusal to answer a household income question in a telephone survey. The household income question is frequently a crucial question in consumer surveys for several reasons. Most obviously, income commonly serves as a dependent var-

iable (to be estimated) for certain classes or groups of consumers. Moreover, income is often used as an independent variable to predict other, often behavioral, variables. In addition, income data are typically used to evaluate the representativeness of a sample by comparing sample income data with criterion (usually population or census) income data. Finally, income is sometimes employed as a surrogate variable or in combination with other variables in index form.

Despite the importance of the income question, nonresponse to income questions tends to be relatively high. Indeed, among demographic or socio-economic variables commonly employed in marketing research surveys it tends to possess the highest refusal rate (Herriott 1977, Locander and Burton 1976). While anecdotal evidence would explain income nonresponse as a function of the "private nature" of income, little empirical evidence exists as to who refuses to answer the income question or why study individuals refuse to answer. The purpose of this paper is to provide insights into both the who and the why questions.

Methodology

Research Data

Data for this investigation were derived from telephone interviews with 6178 adult consumers in a southwestern metropolitan area. Interviews lasted 8-10 minutes and had as their subject matter financial attitudes and behavior. Data collection employed systematic random digit dialing, a dialing technique which gives each household in the specified exchanges an equal probability of being included in the sample (it is a non-directory approach). Two call-back attempts (three attempts in all) were made to contact study individuals, and all interviewing was conducted between the hours of 6-9 p.m. weekdays and 10 a.m. to 9 p.m. weekends. Across all study individuals interviewed the overall refusal rate for the income question was 12.6 percent (779 of the 6178 individuals interviewed).

The dependent variable was refusal to answer an income question. This question was asked in a straightforward manner as "What is your total annual household income?" with five response categories provided. Four demographic characteristics were employed as independent variables: sex, marital status, education, and age. To facilitate data analysis the latter three variables were dichotomized. Marital status response categories consisted of "married" and "not married" (the latter including individuals who were single, divorced, or widowed). The "low" education category included individuals who possessed no college education while "low age" study individuals were those 18-34 years of age. These variables were respectively coded as follows:

Variable	Category	Code
sex	male	1
	female	0
marital status	married	1
	not married	0
education	low	0
	high	1

Variable	Category	Code
Age	low	0
	high	1

Study data are presented in Table 1, which is essentially a four way (16 cell) contingency table. Observed proportions can be interpreted as refusal probabilities. Thus the probability was .087 that a low age, low education, married male refused to answer the household income question.

TABLE 1
Income Question Refusal Probabilities

		Male		Female	
		Married	Not Married	Married	Not Married
Low	Age	.087(160)*	.130(154)	.135(377)	.129(210)
	Educa- tion				
High	Age	.137(256)	.111(54)	.213(451)	.196(179)
	Educa- tion				
Low	Age	.076(618)	.055(814)	.108(741)	.074(717)
	Educa- tion				
High	Age	.153(528)	.120(83)	.181(574)	.183(262)
	Educa- tion				

*Figures in parentheses represent number of study individuals in cell.

Analytical Approach

Due to the nature of the research data (i.e., a discrete dependent variable and a relatively large sample size) a logit model approach was selected as appropriate for data analysis. The particular approach used ECTA, a likelihood ratio analytical model derived by Goodman (1972). Such an approach permits prediction of the probability of refusal to answer the income question (R) as a function of education (E), age (A), sex (S) and marital status (M). Technically the objective of logit analysis is to reduce a "saturated" model which incorporates all independent variable effects at all levels (and which obviously fits the observed data perfectly) into a more parsimonious model that still provides an acceptable fit to the data. The saturated model can be posed in standard ANOVA format as:

$$L_{ijkl}^{\bar{R}} = \mu^{\bar{R}} + \mu_{(i)}^{\bar{E}\bar{R}} + \mu_{(j)}^{\bar{A}\bar{R}} + \mu_{(k)}^{\bar{S}\bar{R}} + \mu_{(l)}^{\bar{M}\bar{R}} + \mu_{(ij)}^{\bar{E}\bar{A}\bar{R}} + \mu_{(ik)}^{\bar{E}\bar{S}\bar{R}} + \mu_{(il)}^{\bar{E}\bar{M}\bar{R}} + \mu_{(jk)}^{\bar{A}\bar{S}\bar{R}} + \mu_{(jl)}^{\bar{A}\bar{M}\bar{R}} + \mu_{(kl)}^{\bar{S}\bar{M}\bar{R}} + \mu_{(ijk)}^{\bar{E}\bar{A}\bar{S}\bar{R}} + \mu_{(ijl)}^{\bar{E}\bar{A}\bar{M}\bar{R}} + \mu_{(ikl)}^{\bar{E}\bar{S}\bar{M}\bar{R}} + \mu_{(jkl)}^{\bar{A}\bar{S}\bar{M}\bar{R}} + \mu_{(ijkl)}^{\bar{E}\bar{A}\bar{S}\bar{M}\bar{R}} \quad (1)$$

where $L_{ijkl}^{\bar{R}}$ is the natural logarithm of the odds ratio refusal probability/nonrefusal probability (the logit) and the μ 's represent the respective independent main and interaction effects.²

To simplify a saturated model M_1 the μ terms are systematically constrained to zero in a step-wise manner and the loss in explanatory power calculated at each step. Selection of terms to be included in the final model is done by simultaneously evaluating their standardized coefficients and explanatory power (variance accounted for). This approach proceeds in a hierarchical fashion with an

independent variable's lower order terms being simultaneously evaluated with significant higher order terms.

Results

Table 2 contains a summary of the logit analysis. The saturated model M_1 has been reduced to the best fit model M_6 through the retention of significant independent variables. Thus model M_6 is given as:

$$\bar{L}R_{ijkl} = \mu \bar{R} + \mu \bar{E}R + \mu \bar{A}R + \mu \bar{S}R + \mu \bar{M}R + \mu \bar{E}A\bar{R}$$

This model explains the probability of income refusal as a function of variation in respondent education, age, sex, marital status and the interaction between education and age. As shown in the last column of Table 2, the model explains nearly 95 percent of the variance in income refusal probabilities. To further investigate model fit, a predicted probability for each cell in Table 1 was computed and compared with the cell's observed probability. Results from this comparison are presented in Table 3. Overall model M_6 fit the data relatively well; the average absolute difference was .013. The relative importance of the independent variables in predicting refusal can be assessed both by the column "Gain in G^2 " in Table 2 and by the estimated standardized effect coefficients in Table 4. The larger the absolute value of the coefficient the greater the magnitude of the effect.

Who Refused to Answer?

Table 5 presents the observed probabilities of refusal associated with the significant effects in model M_6 . In general:

- . respondents possessing lesser amounts of education were more likely to refuse than respondents possessing higher amounts of education;
- . older respondents were more likely to refuse than younger respondents;
- . females were more likely to refuse than males; and
- . married respondents were more likely to refuse than unmarried respondents.

Moreover, the interaction between age and education produced a significant relationship with refusal. Finally, the least likely respondent to refuse to answer the household income question was a young, highly educated, unmarried male. The most likely respondent to refuse to answer was an older, less educated, married female.

Hence, refusal to answer the income question in a telephone survey was found not to be randomly distributed across respondents. Rather it was significantly related to the demographic characteristics investigated.

Why Did They Refuse?

Ten percent of the study individuals refusing to answer the income question were reinterviewed by telephone and questioned as to the reason for their refusal. This resulted in 67 completed reinterviews. By far the most frequent refusal reason given related to "invasion of privacy": 76 percent of the refusals were attributable to perceived privacy invasion. While study individuals giving this answer were found in all demographic categories, nonmarried females were more likely than other study individuals to respond in this manner.

Twenty percent of the study individuals reinterviewed

stated they did not know their annual household incomes. These individuals tended to possess the characteristics of low education, high age, and be married females. Further exploration revealed that the married females were only provided a weekly allowance by their husbands; they were simply not informed as to their husbands' earnings.

Finally, 4 percent of the study individuals reinterviewed said they did not have time to calculate their household income since it would be necessary to take into account a spouse's income as well as "other" income sources. For them responding required too much effort.

In brief, reasons for refusing to answer the income question differed across respondents and also (albeit to a lesser degree) related to demographic characteristics. Thus the results lend support to those of Skelton (1963) with respect to why study individuals refuse to answer an income question.

Conclusion

The present research investigated the relationship between refusal to answer a household income question in a telephone survey and four demographic variables. Using the logit model approach of Goodman a significant relationship was found between each of the four independent variables and refusal to answer. Moreover, reasons given for not answering an income question also differed across the individuals studied.

The implications of these research findings are twofold. First, the mere existence of a relatively large refusal rate for the income question increases the standard error of that variable and impedes investigation of relationships between income and other variables. Second, because nonresponse was not randomly distributed, any estimate of population income from the sample will be biased unless corrections are made. Moreover, any calculated relationships involving income are likely to be distorted due to the differential refusal rates.

Still, while this paper documented income question nonresponse, more research needs to be conducted on item nonresponse in general. Ultimately strategies for effectively reducing as well as handling item response need to be developed and implemented.

THE EFFECTS OF SALUTATION, MONETARY INCENTIVE, AND DEGREE OF URBANIZATION
ON MAIL QUESTIONNAIRE RESPONSE RATE, SPEED, AND QUALITY

Linda L. Golden, University of Texas at Austin
W. Thomas Anderson, University of Texas at Austin
Louis K. Sharpe, Sharpe's Department Store, Checotah, Oklahoma

Abstract

The effects of three cover letter personalization treatments, a cash drawing monetary incentive, and rural, suburban, and urban place of residence upon response rate, speed, and quality for a mail questionnaire were investigated. The results indicated that cover letter personalization treatments did not have significantly different effects on response rate, speed, or quality. The probabilistic monetary incentive lowered response rate, but degree of urbanization moderated the effects on response rate, speed, and quality. Rural, suburban, and urban respondents may be differentially misunderstood by mail survey researchers due to potentially differing degrees of response and nonresponse biases.

Introduction

One of the most commonly used and intensively researched data gathering techniques in the behavioral sciences is the mail questionnaire. However, as two of the most recent review articles point out (Kanuk and Berenson 1975, p. 451; Linsky 1975, p. 100), even with the large volume of research on mail questionnaires, very few systematic conclusions can be drawn about the effectiveness of the various mail survey techniques. This is partially due to inconsistent results across studies, a lack of replication and research on any one technique, a near absence of research designed specifically to compare mail survey techniques in a variety of purposively selected populations, and the lack of a systematic body of knowledge or conceptual framework developed from general theory (Kanuk and Berenson 1975, Linsky 1975).

While the present research does not constitute a replication, nor do the authors pretend to develop a theoretical framework for mail survey research, this investigation does provide additional information on the effectiveness of two mail survey techniques: the personalized cover letter and the cash drawing as a monetary incentive. Moreover, this research compares the effects for respondents from three purposively selected populations: urban, suburban, and rural.

Personalization of Cover Letters

While one review article (Linsky 1975, p. 92) reports 16 studies dealing with personalization of cover letters, a review of these articles and others reveals that the method of personalization varies widely across studies. Personalization treatments have ranged from individually typed letters versus form letters (Simon 1967) to handwritten postscripts forging reply versus no postscript (Frazier and Bird 1958). Similar to figures reported by Linsky (1975, p. 92), of the 20 studies reviewed, 11 reported higher response rates for personalized over impersonal cover letters (Carpenter 1974, Cox, Anderson, and Fulcher 1974, Frazier and Bird 1958, Linsky 1965, Longworth 1953, Moore 1941, Roehrer 1963, Simon 1967), five reported higher response rates for impersonal cover letters (Andreason 1970, Houston and Jefferson 1975, Simon 1967, Watson 1965, Weilbacher and Walsh 1952), and four studies reported no significant differences between personalized and impersonal cover letters (Clausen and Ford 1947, Kawash and Aleamoni 1971, Kimball 1961).

Thus, results for the various forms of cover letter personalization are mixed. Further, the results are also mixed for any particular form of personalization, although almost half as many different forms of personalization were tested as there are number of studies.

The present research focuses on personalization via the inside address and cover letter salutation. Five studies were found which investigated the effects of personalization via either the salutation or the inside address and salutation on response rate. One reported significant differences between personalized and impersonal cover letters favoring the personalized form (Cox, Anderson, and Fulcher 1974), one reported significant differences favoring the impersonal form (Andreason 1970), and three reported no significant differences between personalized and impersonal cover letters (Clausen and Ford 1947, Kimball 1961, and Weilbacher and Walsh 1952). While the results across studies generally indicate no significant effect of personalization, the inconsistent results imply that the research context and topic may be an important factor in the effects of personalization.

Monetary Incentives

Inducements offered to the respondent in an attempt to increase response rate have frequently been in the form of monetary incentives. While studies investigating the effectiveness of premiums (nonmonetary rewards such as a ballpoint pen or trading stamps) have unanimously reported that offering a premium produces a higher response rate than offering no premium at all (Linsky 1975, p. 99), one study found that inclusion of money significantly increased response rate over inclusion of a premium (Goodstadt, Chung, Kronitz, and Cook 1977). "In general, money seems to be the most effective and least biasing incentive, the easiest to obtain and mail, and the most useful to all recipients" (Kanuk and Berenson 1975, p. 447).

There are two broad categories of studies investigating response rates produced by monetary rewards: those investigating a prepaid monetary incentive and those investigating a promised monetary incentive. Of the 20 studies reviewed researching the effects of prepaid monetary incentives, all found that offering a prepaid incentive produced a higher response rate than offering no monetary incentive at all (Armstrong and Overton 1971, Bevis 1948, Blumberg, Buller, and Hare 1974, Erdos 1970, Goodstadt, Chung, Kronitz, and Cook 1977, Hackler and Bourgette 1973, Huck and Gleason 1974, Hancock 1940, Kephart and Bressler 1958, Kimball 1961, Maloney 1954, Newman 1962, Pressley and Tullar 1977, Shuttleworth 1931, Watson 1965, Wiseman 1973, Wotruba 1966). Not all of these studies employed significance tests or reported significant differences; however, it may be concluded unequivocally that a prepaid monetary incentive produces a higher percentage response than offering no monetary incentive. And, as one review article reports, the larger the prepaid monetary incentive, the greater the increase in response rate (Armstrong 1973, p. 111).

Of the five studies investigating the effects of a promised monetary incentive on response rate, three compared

promised, prepaid, and no incentive treatments (Blumberg, Fuller, and Hare 1974; Hancock 1940; Wotruba 1966). All three found small and insignificant differences between promised incentives and a no incentive control, but, as reported above, much larger differences between prepaid incentives and the control. In addition, while promised incentives increased the response rate only very slightly, the prepaid treatment produced a significantly higher response rate than did the promised incentive treatment. One study by Gelb (1975), which did not include a control group, found the prepaid monetary incentives significantly increased response rate over promised monetary rewards for middle-class subjects, while promised rewards produced a higher response rate than prepaid incentives for lower-class subjects. Schewe and Cournoyer (1976) found that against a control of no monetary incentive, the size of the promised monetary reward influenced its effectiveness. Thus, while promised incentives appear to be generally less effective than prepaid monetary rewards, the amount of the promised incentive (Schewe and Cournoyer 1976) and the population sampled (Gelb 1975) may alter or even reverse the general ineffectiveness of the promised monetary incentive.

Research Focus and Purpose

While response rate differences have been examined for a variety of populations, no studies were found in the literature comparing the possible differential responsiveness of rural, suburban, and urban residents to personalized cover letters and monetary incentives. Moreover, no study was identified which compared rural, suburban, and urban mail survey response rates, or any other measure of mail questionnaire response for these populations. These residential groups would be expected to have distinct socioeconomic and demographic profiles; such respondent differences have been shown to correlate with measures of response and nonresponse bias (see Kanuk and Berenson 1975).

The general purpose of this study is to investigate the effects of a cash drawing as a monetary incentive, cover letter personalization and degree of urbanization (area of residence) upon response rate, quality, and speed. Response speed and quality, or degree of questionnaire completion, not only provide additional insight into the response patterns related to the treatments and residential conditions but are also frequently-used measures of response bias. The cash drawing incentive and cover letter personalization treatments are expected to produce higher response rates, speed, and quality than no incentives or no personalization. And, it is expected that urban and suburban residents will have higher response rates, speed, and quality than rural residents. The research also investigates psychographic differences among respondents receiving the monetary incentive who entered and who did not enter the cash drawing, and psychographic differences associated with response speed and quality. It is expected that external locus of control and future-oriented respondents will be more likely to participate in the cash drawing and will have higher response, speed, and quality.

Method

The questionnaire was a three-page inquiry into shopping patterns for basic types of products: groceries, clothing, and furniture and appliances. Since the respondents were likely to be of varied educational backgrounds, the questionnaire was extensively pretested in the field for clarity.

Standard demographic information was obtained and four psychographic measures were included in the final sections of the questionnaire. The psychographic variables measured were: James' Internal-External Locus of Control

(Rotter 1966), Life Satisfaction (Robinson 1977), Attitude Toward the Past, Present and Future (Rokeach 1956), and Traditional Family Ideology (Levenson and Huffman 1955). Life satisfaction and traditional family ideology measures were included only for descriptive comparison among rural, suburban, and urban residents; however, it was expected that locus of control and attitude toward past, present, and future would influence responsiveness to the monetary incentive offered.

The questionnaire was mailed to a sample of 4,500 potential respondents in Eastern Oklahoma, randomly selected from current telephone directories of five trading areas: (Tulsa (n = 1,500), suburbs of Tulsa (n = 1,500), Muskogee (n = 500), Chocotah (n = 500), and Stigler (n = 500)). The last three communities represent the most rural communities sampled. The cover letter, each individually hand-signed, requested that the questionnaire be completed by the person who does most of the shopping in the household.

The two experimental treatments tested in this study, monetary incentive and salutation, were administered via the cover letter. Three thousand of the 4,500 potential respondents received a cover letter which described a drawing for cash prizes totaling \$75.00. One \$25.00 prize, five \$5.00 prizes, and 25 \$1.00 prizes were offered. The respondent was to return a cash drawing card in the postage-paid return envelope provided for the questionnaire if s/he wished to enter the drawing. The cash drawing card was used as the method for entry to allow the respondent to return the questionnaire anonymously without entering the contest. The dollar values of the prizes offered were chosen in order to maximize the respondents' probability of winning a potentially higher dollar-value return. Fifteen hundred potential respondents received a cover letter that made no mention of a monetary incentive but which, in all other aspects, paralleled the monetary incentive cover letter.

The cover letters also contained one of three different levels of salutation. Fifteen hundred potential respondents received a standardized "Dear Shopper" salutation with no inside address. Another 1,500 potential respondents were sent a cover letter with a formally typed complete inside address and "Dear Mr. and Ms. _____" salutation including the respondent's last name. The remaining 1,500 respondents received a handwritten "Dear Mr. or Ms. _____" salutation personalized with the respondent's last name, but with no inside address. The salutation treatments were designed to represent impersonal, formal, and personal salutations, respectively, although the envelopes were all typed and personalized with Mr. or Ms. _____. Respondents were randomly assigned to both the monetary incentive and salutation treatments; assignment was controlled so that each area of residence received the same proportion of each treatment.

Responses were evaluated on three criteria: response rate, speed, and quality. As the measure of success typically used by researchers, response rate was the percentage of the total mailing which was returned, regardless of degree of questionnaire completion. Response speed was measured continuously by the postmark on the respondents' return envelope; the earliest postmark was assigned a value of one. Questionnaires were mailed simultaneously from central Texas, and returns began within a week of the mailing; the range for the response speed variables was from one to 43 days. Response quality was evaluated according to the degree of completion of the questionnaire. Since the questionnaire contained four sections, response quality ranged from one to five: one being a fully-completed questionnaire, four representing only one part completed, and

five a questionnaire with only scattered responses and no sections complete.

Analysis and Results

A total of 833 questionnaires were returned, resulting in a response rate of 18.5 percent. Due to financial constraints, and in order to reach a broader segment of the population, the researchers opted to send questionnaires to a larger sample frame rather than reduce the sample frame size and use a follow-up. The response rate is reflective of what would be expected under no follow-up conditions.

Response Rate

Chi squares were computed for response and nonresponse frequencies for monetary incentive, salutation, and urbanization treatments separately and are presented in Table 1. Surprisingly, the nonmonetary level (control) produced a significantly higher response rate than did the monetary incentive. Slightly over 20 percent of the 1,500 potential respondents who were mailed the nonmonetary cover letter returned the survey, whereas 17.7 percent of the 3,000 potential respondents mailed the monetary incentive returned the survey. Thus, the cash drawing was significantly less effective than offering no monetary incentive.

There was no significant effect for the salutation treatment; all three levels yielded response rates approximating the expected 18.5 percent. However, response rate did vary significantly by urbanization. Urban residents had the highest response rate (21.3 percent) and were the only group whose frequency of response was higher than the expected rate (16.5 percent), while the rural residents had the lowest response rate (15.2 percent).

To investigate psychographic differences among participants and nonparticipants in the cash drawing, the data were submitted to one-way analysis of variance (Nie et al 1975, p. 422) for each psychographic variable separately. As indicated in Table 2 and as expected, locus of control and attitude toward past, present, and future were the only two psychographic variables on which participants and nonparticipants in the cash drawing differed. Respondents returning the cash drawing card were significantly more externally-oriented than respondents who did not return the cash drawing card. In addition, participants in the cash drawing were significantly more future-oriented than nonparticipants.

To investigate differential responsiveness to the personalization and monetary treatments among rural, suburban, and urban residents, chi squares were computed for response and nonresponse frequencies on each treatment separately. Of the six chi squares computed, only one was significant within an alpha level of five percent. The suburban response rate to the monetary incentive was

TABLE 1

^d 1,500 of each treatment level were mailed.

12.6 percent, compared to a 16.6 percent response rate for the control group (chi square of 4.22 with one degree of freedom). Thus, suburbanites responded less frequently than expected (13.9 percent) to the monetary incentive and more frequently than expected (14.0 percent) when there was no monetary incentive. While the suburban response rate was significantly decreased by the monetary incentive, rural and urban response rates did not differ between the monetary incentive and the control. Urbanization groups did not respond significantly differently to the cover letter personalization treatment levels.

Response Speed and Quality

In order to investigate the effects of the monetary incentive and salutation treatments and the urbanization condition upon response speed, the data were submitted to three-way analysis of variance (Nie et al 1975, p. 410). Table 3 shows the results of these analyses.

Neither treatment produced a significant main effect, and there were no significant interaction effects. There was, however, a significant main effect of urbanization. Contrary to expectations, rural respondents returned the questionnaire more quickly than either the suburban or

the urban respondents, respectively. Scheffé tests (Scheffé 1959, p. 477) indicated that both rural and suburban respondents responded significantly more quickly than did urban respondents, although there was no significant difference in mean response speed between rural and suburban respondents. Thus, while urban respondents had the highest response rate, they were the slowest to

respond. Rural respondents showed just the reverse pattern: the lowest response rate but the quickest response speed.

Table 4 presents the results of the three-way analysis of variance (Nie et al 1975, p. 410) for the effects of the monetary incentive and salutation treatments and the

urbanization condition on response quality. Again, there were no significant main effects for monetary incentive or salutation treatments and no significant two- or three-way interactions. Urbanization was the only variable which produced a significant main effect. The urban respondents had the highest response quality, followed by the suburban and rural respondents, respectively. Scheffé tests indicated that the rural respondents had a significantly lower quality of response than both the suburban and the urban respondents. There was no significant difference between urban and suburban response quality. Thus, while urban respondents were relatively slower respondents, they were relatively thorough in their questionnaire completion. Rural respondents, on the other hand, were relatively more quick to respond, but questionnaire completion was lower. The suburban respondents continually fell in the middle, aligning themselves with the rural respondents in terms of speed and the urban respondents in terms of quality. Suburban response rate also tended toward the lower response rate of the rural residents.

The data for the psychographic variables and response speed and quality were submitted to correlational analyses (Nie et al 1975, p. 280). Table 5 presents the results of these analyses. Response speed was significantly correlated with locus of control and family ideology, although the Pearson correlations were not high. Response speed was significantly correlated with three of the four psychographic variables: locus of control, family ideology, and attitude toward the past, present, and future. Life satisfaction was not significantly related to either response speed or quality. The correlations of the significant psychographics with response quality were much higher than the correlations with response speed.

The more external the respondent's locus of control, the slower to respond and the lower the response quality. Respondents with a more internal locus of control responded more quickly and had a generally higher degree of questionnaire completion than did the respondents who were relatively more external. Further, the more

traditional the family ideology, the faster the response speed and the lower the quality of response. The respondents with the least traditional family ideologies responded more slowly but with a higher completion rate than did the respondents with a relatively more traditional family ideology. For response quality, the more past-oriented the respondent, the lower the quality. Thus, the more future-oriented respondents provided the most complete questionnaires; however, this psychographic was not significantly associated with response speed.

Conclusions and Implications

This study investigated the effects of cover letter personalization, a promised and uncertain monetary incentive, and degree of urbanization upon response rate, speed, and quality for a mail questionnaire. The results suggest that the additional costs of cover letter personalization are not warranted if the researcher's objective is to increase response rate, speed, or quality. While the conclusions drawn from this study must be restricted to the sample under investigation and the specific treatments used, these results are consistent with those obtained by three of the five studies using the salutation as the method of personalization (Clausen and Ford 1947, Kimball 1961, Weilbacher and Walsh 1952). In addition, this study indicates that rural, suburban, or urban residence does not influence the effects of personalization.

A cash drawing monetary incentive appears to decrease response rate in contrast with no monetary incentive. There may be a raffle effect which results from this type of monetary incentive, whereby potential respondents may regard the questionnaire as just another piece of "junk mail," decreasing the researcher's credibility. However, there were no differences between the monetary treatment and the control for response speed and quality. Thus, according to this study, the uncertain promised monetary incentive has no redeeming virtues.

Rural and urban respondents do not appear to be differentially responsive to uncertain monetary incentive treatments, but suburban respondents may be, as they returned the control treatment questionnaires at a significantly higher rate than the monetary incentive questionnaires. Thus, while rural and urban respondents did not tend to react negatively to the cash drawing, at least as evidenced by their response rate, suburban respondents evidenced the strongest "raffle effect reaction."

Respondents who received a "raffle" monetary incentive and returned the cash drawing card appear to be different from those who do not return the cash drawing card. Respondents returning the cash drawing card were significantly more external in their locus of control and significantly more future-oriented than nonparticipants in the cash drawing. Externally- and future-oriented persons may be more "raffle prone" and more likely to take a "gamble" than persons with other orientations, thus making them the most likely to be responsive to the type of incentive investigated here. If the researcher has prior knowledge of a sample's psychographic characteristics, an uncertain monetary incentive may be able to reduce the costs of a monetary "reward" and possibly increase response rate.

Urbanization appears to have an important and significant influence upon response rate, speed, and quality. Urban residents had the highest response rate, were slowest to respond but provided the highest quality responses. Rural residents were a mirror image of the urban residents, providing the lowest response rate, the quickest response, and the lowest response quality. Consistent with their mid-range urbanism, suburban respondents occupied the middle. Suburban respondents aligned themselves with rural respondents on response speed and with urban respondents on response quality.

Response rate and quality differences among rural, urban, and suburban residents may be partially explained by demographic differences, specifically education.¹ With the highest educational level, urban residents may be more experienced communicators resulting in a higher response rate and response quality than for either suburbanites or ruralites. In addition, the ruralites, with the lowest educational level, would be expected to be the least responsive to mail surveys both in terms of response rate and quality. Such was the case.

Response speed and quality provide some response bias information for the three residential groups. The late respondents to a questionnaire sampling the three urbanism groups were more likely to be urban; thus, the nonrespondents may tend to be more like the urban population sampled although the urban residents do respond at a higher rate. Because of their low quality of response, however, the researcher is likely to obtain the least information from rural samples. Coupled with their low response rate, the low quality of responses make these respondents the least understood, or most misunderstood, of the three groups. They are, in fact, the least represented in this study both in terms of response and nonresponse bias.

Response speed and quality tend to be associated with certain psychographic characteristics. Respondents who were the slowest to respond were more external in their locus of control and less traditional in their family ideology. In addition, respondents who provided the lowest response quality in terms of survey completion were more externally-oriented and more traditional in family ideology, as well as being more past-oriented than respondents with higher quality responses. Thus, without taking place of residence into consideration, the nonrespondents (to the extent that they are similar to late respondents) are likely to be more external in their locus of control and less traditional than respondents. However, the measure of response bias indicates that the least complete questionnaires are likely to come from more externally-oriented respondents and those with a more traditional family ideology.

The resounding implication of this study is the importance of the population sampled and the subsequent effect upon mail questionnaire response rate and potential bias in terms of response speed and quality. Researchers sampling across two or more of these populations are advised that they may have differing response patterns which should be taken into consideration in adjusting for any potential biases. Rural populations may be the most misunderstood, while urban populations may be the most represented and the least misunderstood. Wave mailing of questionnaires should also consider the unique characteristics of these populations when determining the timing of questionnaire waves. Rural, suburban, and urban samples cannot be considered to be drawn from the same populations. Although potentially the least costly, mail questionnaires may be the least effective means of sampling rural populations.

WHAT IF OPINION LEADERS DIDN'T KNOW MORE?
A QUESTION OF NOMOLOGICAL VALIDITY

Jacob Jacoby, Purdue University
Wayne D. Hoyer, Purdue University

Abstract

Given the numerous investigations involving opinion leadership, it is surprising to find that the construct validity of this important concept has yet to be firmly established. While a few studies present evidence for convergent and discriminant validity, no data appear to exist bearing on nomological validity. The present investigation addressed this issue by examining a predicted relationship between opinion leadership and expertise. Results show a strong positive correlation between these two concepts, thereby providing support for the concept of opinion leadership. While this study represents only a brief methodological note, had the hypothesis not been confirmed, the implications would have been substantial.

Introduction

The concept of opinion leadership has been the subject of numerous investigations in a variety of fields, including consumer behavior, social psychology, communications, marketing, and sociology. Most of these studies have attempted to isolate social activity, general attitudes, demographic, personality, and life style characteristics in order to gain a better understanding of just who opinion leaders are and how they influence others in society (Engel, Blackwell, & Kollat 1978).

A major problem with this body of research is that the concept of opinion leadership is accepted uncritically; not much empirical evidence exists to establish the construct validity of this important concept (Jacoby 1974). In order to establish construct validity, one needs to show the extent to which the measures of the construct "fit into a network of expected relations" (Nunnally 1978). This requires demonstrating that: (1) different measures of the same concept are highly related (convergent validity); (2) measures of the same concept are correlated more highly with each other than with measures of totally different concepts (discriminant validity); and (3) the measures of this concept bear some relationship to measures of other constructs which are hypothesized to be related to the concept in question (nomological validity; Campbell 1960).

Virtually all efforts at operationalizing opinion leadership can be reduced to three basic techniques. The self-designation method asks the respondent to judge whether or not he himself is an opinion leader. The key informant approach involves, first, the identification of individuals who are assumed to be knowledgeable of the social interactions within a particular group and, second, having these key informants indicate which members of the group are opinion leaders. Finally, the sociometric method involves interviewing all members of a particular group in order to determine the nature of the social interactions within the group and thus identify the opinion leaders.

The first step in construct validation is to establish the extent to which these measures are related (i.e., convergent validity). Some evidence for convergent validity already exists. Katz and Lazarsfeld (1955) found

a strong positive relationship between the self-designating and sociometric approaches. Rogers and Catarno (1962) described data from an unpublished doctoral dissertation which revealed a positive correlation across all three measures. The problem with these studies, however, is that evidence was only provided for convergent validity and no attempt was made to establish discriminant validity.

A subsequent study by Jacoby (1974) applied the Campbell and Fiske (1959) multi-method multi-trait approach to determine both the convergent and discriminant validity of opinion leadership as this was manifested by the women in four large campus sorority organizations. Results showed that "the four coefficients pertinent for assessing convergent validity were surprisingly high in view of the limits that reliability places on validity." Discriminant validity was adequately established for only two of the four groups tested in the study. In general, however, there would appear to be at least some evidence for both the convergent and discriminant validity of opinion leadership.

What still needs to be determined, however, is the extent to which measures of opinion leadership are related as predicted to measures of other conceptually specified constructs (i.e., nomological validity). For example, it seems to be generally assumed that opinion leaders actually possess more knowledge or expertise in the product category of interest than do members of the general population. That is, it seems logical that individuals who are sought out and considered useful sources of information regarding an issue or product category would, in fact, possess a somewhat higher level of knowledge regarding the issue or product category. Evidence for nomological validity would therefore be supplied if a measure of opinion leadership in a particular product category would correlate positively with a measure of actual knowledge regarding that product category. The purpose of the present study was to determine the extent of this relationship and to hopefully be able to provide some degree of evidence for nomological validity which had been previously lacking.

Consumer researchers (e.g., Abelson, et al. 1974, Valenzi and Andrews 1973) have usually measured "knowledge level" or expertise by asking respondents to provide a self estimate of the degree of their knowledge. Researchers are increasingly finding, however, that individuals are not accurate judges of their own knowledge level or ability. For example, De Nisi and Shaw (1977) found that self ratings of ability correlated very poorly with scores on an actual ability test and that self-ability ratings were unable to differentiate between those of high and low ability.

The present study avoided this problem by using a 30 item stereo knowledge test developed by Jacoby and Williams-Jones (1973). This instrument was pretested on 50 undergraduates. Results showed "that scores fell into 3 distinct groups, with approximately one tenth of the scores being clearly higher than the rest and another one fifth falling much lower than the majority of subjects whose scores formed the center of the distribution" (Williams-Jones 1974, p. 16). For purposes of validation, this

test was next administered to a sample of 12 stereo repairmen and technicians, all 12 of whom scored in the "expert" range. Given these results, it was felt that testing expertise via this instrument was preferable to asking respondents to provide a judgment regarding their level of expertise.

In summary, the present study attempted to examine the nomological validity of opinion leadership by testing the relationship between this construct and another construct believed to be logically related, namely expertise. The specific hypothesis being tested was: Opinion leadership in regard to stereo equipment is positively related to knowledge about the product category.

Method

Subjects - One hundred thirty one students (72 males and 59 females) enrolled in an introductory psychology course at a large midwestern university served as subjects in this study. Participation served as partial fulfillment of a course requirement.

Procedure and Measures - Each subject filled out a three part questionnaire. The first part consisted of Jacoby's (1972) seven item self-designating measure of opinion leadership. This index differs from the more traditional measures (e.g., King and Summers 1970) in having seven rather than six questions and more response options (for improved reliability) for each question. Apropos of our earlier comments regarding the frailty of verbal report instruments and our comments elsewhere regarding the necessity for multiple indicant research (Jacoby 1976, p. 7), it should be noted that the convergent validity between this index and separate sociometric and key informant indices was found to be quite high (cf. Jacoby 1974). This previous research provides the rationale for employing only a single indicant approach in the present investigation.

To provide additional perspective on the findings, the second section of the questionnaire consisted of five questions which asked subjects: whether they had ever owned any stereo equipment both in the past and presently, whether they had ever been in the process of looking for stereo equipment, the last time they purchased any equipment, and how much they felt they knew about stereos.

The final portion of the questionnaire contained the stereo knowledge test developed by Jacoby and Williams-Jones (1973). The test consisted of 16 multiple choice and 14 matching questions covering a variety of facts about stereo equipment (see Appendix A).

Results

The Pearson product-moment correlations between the measure of opinion leadership, stereo knowledge, and the other assessed variables are presented in Table 1.

Opinion Leadership and Expertise

The most significant finding is that opinion leadership scores correlate as one would expect with expertise ($r = .69, p < .001$). That is, the tendency to be an opinion leader for stereo equipment is highly related to one's knowledge about stereo equipment.

Opinion Leadership and Past Experience

Also as might be expected, a positive correlation ($r = .32, p < .01$) was found between past stereo ownership and opinion leadership. In other words, opinion leaders were

somewhat more likely to have owned stereo equipment in the past than were non-opinion leaders. Further, opinion leaders were more likely to currently be in the process of looking for stereo equipment than non-opinion leaders ($r = .50, p < .01$). There was either a low or no correlation between opinion leadership and either present ownership, number of years owned, years since most recent purchase, or whether the respondent believed he had greater knowledge at the time of the first purchase or now.

Expertise and Past Experience

A low positive correlation was found between expertise and past ownership ($r = .25, p < .05$). In addition, "experts" were somewhat more likely to be currently looking for stereo equipment than were "nonexperts" ($r = .33, p < .01$). Consistent with the findings for opinion leadership, the other dependent measures exhibited little or no correlation with expertise.

Sex Differences

As expected, expertise correlated negatively with sex of subject ($r = -.69, p < .001$). Females were far less likely to be "experts" for stereo equipment than were males.

Sex of subject was also correlated negatively with opinion leadership ($r = -.44, p < .01$). That is, females were also less likely to be opinion leaders with regard to stereo equipment.

In view of these findings, the main analysis was further subdivided according to sex. Table 2 presents the Pearson correlations for males and Table 3 for females. It can be seen from these Tables that, in the case of males, the correlation between opinion leadership and expertise was almost identical to the previous result ($r = .66, p < .001$). The female correlation was substantially lower ($r = .27, p < .05$). Thus, the relationship between opinion leadership and expertise for the stereo product class appears to be sex-specific.

Product Involvement

Finally, it is always possible that the link between opinion leadership and expertise is a reflection of a third variable. One logical possibility for such a third variable is involvement with the product category and several of the variables that were assessed (e.g., looking to purchase, ownership) appear to tap such a dimension. Table 4 presents partial correlations which control for these "involvement" variables. As shown in Table 4, the relationship between opinion leadership is not significantly lower when these variables are held constant. Thus, these data do not support the third variable hypothesis insofar as the two variables examined are concerned.

Discussion

As hypothesized, opinion leadership was found to be highly related to expertise. This finding is noteworthy for two reasons. First, it has long been assumed that opinion leaders were more knowledgeable in their area of leadership but this key assumption seems to have never been tested. The present findings provide the missing empirical support.

More importantly, this finding can be viewed as evidence for the nomological validity of opinion leadership. In other words, the measure of opinion leadership did in fact bear a predicted relationship to the conceptually related concept (expertise). If one also includes the findings that opinion leaders were more likely to have

owned stereo equipment in the past and that they were more likely to be presently looking for such equipment, even more confidence can be placed in the nomological validity of the concept. Since stereo equipment is a more male oriented area, the finding that opinion leadership and expertise are strongly related to sex can also be interpreted as support for nomological validity.

Several considerations, however, must be kept in mind when interpreting the results. First, this assessment was performed for only one product category. Research is needed to determine whether this relationship holds for other product categories and subject matters as well. More importantly, stereo equipment is an area which can be considered highly technical. As a result, the difference between expert and non-expert becomes much more distinct. There may be areas or product categories where this distinction is not clear and these areas may not produce as strong results. Relatedly, the product category is highly male oriented. Research is needed to determine if the same pattern exists in female dominated and more neutral or non-sex typed areas.

Another issue concerns the fact that technical knowledge may be only one of several factors which jointly determine expertise. Other expertise oriented factors which may be

equally or more important for the opinion leader to possess include such things as knowledge regarding where to purchase, how much to pay, suitability for various purposes, etc. These factors also warrant empirical attention.

In conclusion, the results of this study, when coupled with the results of the other studies mentioned earlier, seem to indicate a satisfactory degree of validity for the construct of opinion leadership. While it hardly comes as a surprise to find that those who rate themselves as a good source of advice regarding stereo knowledge also have a basis in knowledge for that advice, had this relationship not materialized, the implications would have been substantial. Thus, while only a brief methodological note, this study provides evidence for a critical, but heretofore empirically neglected assumption.

Appendix A: Stereo Knowledge Test*

- B 1. The best stylus (needle) material is:
a. sapphire b. diamond c. ceramic d. ruby
- D 2. The two most commonly used turntable speeds are:
a. 16 and 45 b. 33 and 45 c. 45 and 78
d. 33 and 78
- B 3. A receiver includes all but which of the following?
a. pre amp b. cartridge c. power amp d. tuner
- B 4. Stereo records should ideally be stored:
a. horizontally b. vertically c. near heat
d. without the abrasive dust cover
- C 5. Which of the tracking forces below would probably indicate the highest quality cartridge?
a. 3.0 grams b. 1.0 grams c. .5 grams
d. .75
- C 6. Distortion refers to:
a. unwanted random sound in electronic equipment often heard as a hiss
b. the extent to which a speaker distributes the acoustical power widely to the listening area
c. unwanted sound resulting from the inability of the stereo system to exactly reproduce the tonal qualities of the input
d. a wavering of pitch which is due to minute variations in turntable or tape speed
- D 7. A two-way speaker would not contain:
a. a cross-over network b. a woofer
c. a tweeter d. a mid-range
- C 8. Low efficiency speakers should ideally be paired with a:
a. lower powered amplifier
b. manual turntable
c. higher powered amplifier
d. automatic turntable with magnetic cartridge
- D 9. Which of the following would be the best speaker dispersion pattern? (S=location of the speaker)

*The correct answers are indicated in the response blanks.

- D 10. When turning the balance control to the right:
 a. it increases the right channel (speaker) volume
 b. it decreases the treble volume
 c. it increases the bass volume
 d. it decreases the left channel volume
- C 11. A preener is:
 a. an electrical network designed to eliminate selected frequencies
 b. a fine brush used to clean the cartridge
 c. a type of brush used to clean records
 d. a device which changes AC to DC
- C 12. Which of the following speakers would be most likely to contain a thin sheet of mylar as the diaphragm?
 a. bass reflex b. acoustic suspension
 c. electrostatic d. folded horn
 e. Dolby speaker
- C 13. If you are living in a major metropolitan area, which of the attributes of a tuner is least important to you?
 a. AM rejection b. selectivity c. sensitivity
 d. resistance to overload
- B 14. The purpose of the loudness (contour) control found on most receivers is to:
 a. increase or decrease volume to a greater extent
 b. mainly compensate for loss of bass at low volume settings
 c. mainly compensate for loss of treble at low volume settings
 d. increases the output of the mid-range speakers
- A 15. A system that reduces tape hiss is called a:
 a. Dolby b. tape monitor c. limiter
 d. rectifier e. Hirsch-Houk system
- D 16. There are three methods of rating power commonly used by manufacturers of high fidelity components. A typical amplifier rated under the three different methods would probably have which of the following?
 a. RMS rating 80 watts
 IHF rating 125 watts
 IHF + 1db rating 120 watts
 b. IHF rating 80 watts
 IHF + 1db rating 100 watts
 RMS rating 125 watts
 c. IHF + 1db rating 80 watts
 IHF rating 100 watts
 RMS rating 125 watts
 d. RMS rating 80 watts
 IHF rating 100 watts
 IHF + 1db rating 125 watts
- G 7. gain
J 8. AM tuning range
P 9. infinite baffle
B 10. adequate signal to noise ratio in a pre amp
C 11. bandwidth
Q 12. compliance
U 13. balance control
R 14. IPS
- E. 20 Hz to 20 kHz \pm 1 dB
 F. 88 mHz to 108 mHz
 G. amount of amplification
 H. distance between poles of a magnetic field
 I. speaker that reproduces bass frequencies
 J. 550 kHz to 1600 kHz
 K. 100 Hz to 10kHz \pm 3 dB
 L. reflection of sound (from walls, etc.)
 M. 3 dB
 N. a low frequency vibration mechanically transmitted to the tone arm and pick-up and thus superimposed in the reproduction
 O. wavering of pitch which is due to minute variations in turntable or tape speed
 P. air tight speaker enclosure containing a bass speaker with a very low open air resonance, plus a sealed mid-range and tweeter
 Q. how well a cartridge follows the record groove
 R. speed at which a tape moves
 S. a control which mechanically lifts the tonearm off the record
 T. a total confusion of frequency input
 U. governs relative volume from left-right speakers

Please match the following with the lettered phrases at the right.

- E 1. an adequate frequency response of a power amp
F 2. FM tuning range
O 3. WOW
I 4. woofer
D 5. image
S 6. cueing
- A. ability of a tuner to reject unwanted FM interference on same frequency
 B. 65 dB
 C. range of frequencies occupied by a signal
 D. any reception not occurring at the proper frequency

A DISCUSSION OF SURVEY RESEARCH

James H. Barnes, Jr., The University of Georgia

Introduction

The three papers presented in this session are loosely tied together since each deals with some aspect of survey type research. The differences among them, however, make each very difficult to compare and contrast. Consequently, after presenting some concerns about each paper, I shall attempt in a separate section of this discussion to offer some observations on the state of consumer survey research which I hope will be of some use to the audience of this section. No attempt is made to evaluate the net worth nor the relative contribution of the papers since each reader is probably a better judge of that given his or her particular frame of reference.

Peterson, Leone and Sabertehrani

The authors of this paper deal with the nagging problem of refusal of respondents to provide information relative to family income. This non-sampling error they point out is often encountered in telephone surveys. Three reasons for refusal emerged from the study. Foremost, respondents viewed the question as an invasion of privacy. Second was the fact that they lacked knowledge of their annual household income and finally, they felt that they did not have time to calculate their total income since it was made-up of several different components. The authors also point out that the refusal rate differed across respondents.

While the paper is interesting and generally well-written, the reader is given the impression that the authors are taking an analytical technique and looking for a set of data "crunch". This of course is not necessarily bad since researchers should have an interest in research methods per se. As a methods paper, it would be interesting to see how application of the logit analysis provides greater insight into the data than, for, example, simple cross-tabs of the data set. The use of the logistic function has been found to represent the data when the dependent variable is an indicator variable such as the probability used in the present case. The application of the logit approach presented in this paper is a standard application except perhaps for the conversion of the independent variables to be all 0-1 dummy variables. The authors fail to point out the problems of collapsing the independent variables into categories. While this approach is generally motivated around maintaining cell sizes, real analysis problems can and often do arise.

A second methodological concern is one of the choice of final model arrived at by the authors. The "saturated" model with which the authors begin is one which contains all independent variables as well as all interaction terms. From this model, the technique used reduces the model on the basis of loss in explanatory power. This however, presupposes that the variables education, age, sex, and marital status were the correct variables to begin with. The reader is not informed as to why these particular respondent characteristics were chosen.

Golden, Anderson and Sharpe

Response rate, speed of response and quality of response have long been of vital importance to users of mail survey instruments. In this article, the authors investigate the effects of monetary incentive, salutation and habitancy on

these response measures. The type of salutation is varied by three levels and a probabilistic incentive is offered to a portion of the respondents. Also, the authors evaluate the self-selection variable of habitancy and have the respondents answer four psychographic measures along with the standard demographic questions. The authors conclude that an apparent raffle effect of the monetary incentive tends to decrease response and that urbanization has an influence on response rate, speed, and quality of response.

An important task in any experiment is to control for external factors which can influence the dependent variable. In the present study, the authors use the postmark date on the respondent's return envelope as their measure of response speed (the surveys were sent from a single Texas location to four different eastern Oklahoma areas). The problem is, that this measure is probably influenced to a large extent by the time required for the Postal Service to deliver the mail to the respondent. While I am not familiar with the postal procedures of Texas-Oklahoma, I have had some experience with the variance of postal speed between and within Athens (rural) and Atlanta (metropolitan), Georgia. I suspect that a wide variance also exists in the subject study area of Oklahoma.

Response quality was measured on a one to five scale depending on how many of the four sections of the questionnaire were answered. The selection of this approach is not clear since most prior studies have selected percent of questions completed as a quality measure. This could affect the results reported in Table 4 since the mean quality varied only over the range 1.09 to 1.32. The assignment of a one to five value tends to mask small differences making them appear more significant than otherwise. For example, if a respondent completes only half of one part of the questionnaire does he get a value of four or five. The effect on the computation of the mean is obvious. Also, the authors fail to discuss what types of questions were asked in the four sections of the study. Based on the affiliation of the third author, one would suspect that the questions related to department store shopping. Could rural, urban and suburban residents have different views of department stores which would effect their interest in responding? This, of course, would have affected the measures of rate and quality. Stated differently, are these measured results questionnaire specific.

The theoretical connection between the rather global psychographic measures used and the dependent measures under study is not clear. For example, why does one expect a relationship between external locus of control and response speed? More specific measures of lifestyle would probably have been more useful.

Finally, does the procedure for entering the cash drawing force the respondent to give up anonymity? If both the questionnaire and the entry card are in the same envelope, then one would suspect that this could have some bearing on whether or not one chose to enter the drawing. Also, did many respondents attempt to enter the cash drawing without returning a questionnaire.

Jacoby and Hoyer

In this paper, the authors address the construct validity of opinion leaders. That is, they ask the question, what if so-called opinion leaders really don't know more?

Specifically, Jacoby and Hoyer test the relationship between the opinion leader construct and expertise, another construct believed logically related to opinion leadership. The authors found that as expected, opinion leadership was highly related to expertise.

The link between opinion leadership and expertise has been implied to be one of causality. That is, a person is an opinion leader because he is more of an expert. Although the authors do not deal with the causality issue directly, one could argue that both opinion leadership and expertise are products of another variable namely involvement with the product category. Thus, correlation between opinion leader and expertise would result. Several of the variables used in the present study could be proxies for product category involvement. In fact, by checking the correlation matrix in Table 1, one can note the high correlation between the involvement proxy looking and both the expertise and opinion leader variables. Also, one can see a high correlation between opinion leader, expertise and past ownership, but, low correlation between present owner. This would also suggest involvement since past owners may be in the looking process thus more involved than present owners who are not in the search process.

One would suspect that opinion leadership is a multi-dimensional concept. Such things as where to buy, price, and suitability for various uses and perhaps even more importantly, source credibility. The present study looks at only the link between technical expertise and opinion leaders. Future research should consider these other factors.

Some General Comments About the Area

More years ago than I sometimes care to remember, I was trained in the field of electronic engineering. A favorite training tool of my mentors was to give the student a black-box which contained some form of circuit. However, the student had only the opportunity to manipulate the input terminals of the box. He did not know what was inside. The approach that one must take in analyzing the box was to input various currents and voltage patterns then measure the resultant output. Based on certain principles or laws of electronic components, one could, through manipulating the input and measuring the outputs, determine, within limits, the internal make-up of the circuit components inside the box.

The above story holds, I think, a lesson for us in survey research. A very brief review of the literature reveals over 132 studies of things such as effects of cover letters, postage, incentives, offer of survey results, and other factors on response rates for mail surveys. My point is that we are really like the student above, but we have failed to accomplish the final important task. That is, we are really only looking at the output patterns of the black box as a result of various inputs (manipulations). Continued focus on only outputs puts this research topic into the realm of "learning more and more about less and less." What is needed, is for us to take that next step and infer something about inside the black box (survey respondent). In the studies reviewed above, I questioned several authors about their choice of independent variables. In fact, neither I nor the authors here really have very firm ground for discussing which variables are or are not important. In short, we really don't have a theory on which to base our studies. Thus, my final plea to the reader is that we proceed to combine our multitude of results and determine the circuit inside survey respondents. This, of course, is no easy task, but, a necessary and much needed one at this time in our development.

MULTIATTRIBUTE SCALING MODELS: SOME OBSERVATIONS

Naresh K. Malhotra, Georgia Institute of Technology

Abstract

Some observations are made on four issues which deserve more attention in conjoint analysis and multidimensional scaling research. These issues concern the use of metric vs. nonmetric techniques, robustness of multiattribute scaling models, cognitive processes underlying these models and the role of individual variables.

Introduction

Over the last decade multidimensional scaling and conjoint measurement have become extremely popular for assessing consumers' perceptions and preferences. Due to their popularity, the multiattribute scaling models have also filtered into the annual conferences of the Association for Consumer Research. The last several conferences have featured papers and/or sessions on this topic. Hence, it was only appropriate that the current conference also include a session on this important area.

However, several issues concerning the multiattribute scaling models remain unresolved or even virtually untouched. Some observations are offered on four such issues: the use of metric vs. nonmetric estimation procedures, the robustness of multiattribute scaling models, the cognitive processes underlying these models and individual differences impinging on these models. No attempt is made to offer comprehensive reviews on each of these issues. Rather, the observations made point to, in the opinion of the author, the crux of the issues involved. It is possible that some of the author's views may not be shared by others working in this area. Also, the choice of these specific issues was influenced more by the author's familiarity and experience with them and does not necessarily reflect their intrinsic importance. Some of these issues have also been dealt with in the papers presented in this session.

Metric vs. Nonmetric

The issue of concern is whether the nonmetric techniques are generally superior to the metric procedures for estimating parameters in multiattribute scaling models. The nonmetric techniques assume that the dependent variable or input data is ordinally scaled or weaker. The metric procedures, on the other hand, are based on the assumption that the dependent variable or input data is at least intervally scaled. A brief discussion of the popular metric and nonmetric estimation procedures for conjoint analysis may be found in Green and Srinivasan (1978). An excellent classification of alternative metric and nonmetric multidimensional scaling procedures for analyzing perceptions and preference data is provided by Green and Rao (1972, p. 13). In the context of conjoint analysis, simulation studies (Carmone, Green and Jain 1978; Cattin and Wittink 1976) as well as empirical studies (Jain et al. 1979; McCullough 1978; Montgomery, Wittink and Glaze 1977) have found that the metric OLS regression does as well as the other nonmetric estimation procedures. In the case of multidimensional scaling also, the nonmetric and metric techniques yield very similar results. This is particularly true if the scaling has been done in correct dimensionality (Green 1975). Moreover, certain flexibilities offered by the nonmetric procedures such as the use of alternative distance functions have turned out to be more

of illusory benefits. The recent findings by Hauser and Koppelman (1979) also should make us pause and take a hard look at the nonmetric multidimensional scaling techniques.

In terms of user-oriented criteria such as algorithm availability, adaptability in the user's system, extent of preprocessing of data, and computing costs, the simpler metric procedures may offer some relative advantages (Jain et al. 1979). Further empirical evidence on the relative performance of metric and nonmetric procedures is needed. However, at this stage, it is reasonable to conclude that the general superiority of the more complex nonmetric procedures over the simpler metric procedures has not been so far demonstrated. It is true that in certain situations, particularly where the input data should be treated as only ordinal, the use of nonmetric techniques would be more appropriate. However, consumer researchers must safeguard against the tendency to automatically employ nonmetric procedures in every situation just because they appear to be more sophisticated.

Robustness

The various issues related to reliability and validity of conjoint analysis have been dealt well by Green and Srinivasan (1978). This discussion would focus on only the robustness of conjoint analysis and multidimensional scaling solutions with respect to incomplete or missing data. As the percentage of data (based on all possible observations) obtained from the respondents increases, the reliability and stability of the estimated coefficients should increase and the error in prediction should decline. On the other hand, obtaining large amount of data from the respondent in a given unit of time could cause fatigue and information overload.

Carmone, Green and Jain (1978) undertook a Monte Carlo simulation to examine the effect of missing data on part worth recovery in conjoint analysis. They varied the number of observations at four levels 18, 27, 54, and 243 (full factorial). Thus, the percentage of missing data was varied from 92.6% to 0%. Their results indicated that the part worths recovery was almost as good with 18 observations as with the full set of 243 observations. In a recent empirical investigation, Leigh, Mackay and Summers (1981) investigated the relative performance of full, half and quarter factorial designs. Their study suggests that the less fractionated design tends to produce higher test-retest part worth reliabilities when the number of attributes is limited. Of course, with a larger number of attributes and levels, the less fractionated designs become impractical and the researcher may be forced to adopt the more fractionated designs accommodating a higher percentage of missing data.

In the context of multidimensional scaling, the empirical study by Jain, Malhotra and Mahajan (1978) revealed that configuration recovery became significantly poorer as the percentage of missing data increased from 20% to 40% to 60%. However, the effect of employing cyclical designs or random method of selecting judgmental pairs on which information was obtained was not found to be significant. Similar results were obtained in the Monte Carlo simulation performed by Spence and Domoney (1974).

In sum, it seems that the strategy of collecting incomplete data to minimize respondent task involves trade-offs.

While the collection of incomplete data from the subjects does reduce respondent fatigue, information overload and costs of data collection, it may not adequately capture the underlying perceptions and preferences. However, the question of how such trade-offs are to be made is far from settled. Further empirical research is needed in this area.

Cognitive Processes

The cognitive processes underlying the formation of consumer's perceptions and preferences have not received due attention from marketing researchers employing conjoint analysis and multidimensional scaling techniques. The major issue here is whether and to what extent the model assumed to estimate parameters represents the actual decision process employed by the individual. In conjoint analysis, for example, a particular decision rule, such as the additive or interactive, is assumed to estimate the parameters of the individual's preference function. This has generally been done without adequate regard to the actual choice rule employed by the respondent. Then, post estimation attempts are made to justify the model used as being appropriate. The additive model has been the most popular. The use of a goodness or badness of fit measure, for example Kruskal's stress (1965), as well as the prediction criteria, to determine the appropriateness of the linear model has been rather misleading. Studies have shown that the additive model can yield good fits even when the data corresponds to other decision models (Dawes and Corrigan 1974; Green 1968). Furthermore, the correlational methods used to assess predictive ability suffer from several problems which limit the usefulness of these methods for examining the appropriateness of alternative decision rules. A discussion of the problems involved may be found in Bettman (1979, pp. 191-193).

An algorithmic development which somewhat alleviates this problem is the multistage decision process model by Srinivasan (1977). This is a general model which captures many of the decision rules considered in information processing literature. By taking a multistage view of the consumer decision process, Srinivasan's model takes us a step closer to modelling the actual choice process.

While past attempts have been lacking in this respect, future use of multiattribute scaling models should attempt to formulate estimation models based on the actual decision process adopted by the individual. An approach to accomplish this has been advocated by Olshavsky and Acito (1980).

Individual Variables

The formation of perceptions and preferences is affected by individual differences (Bettman 1979). Simplistic as this statement may seem, conjoint analysis and multidimensional scaling analysis have, hithertofore, not directly focused on such differences. Individual differences related to information processing would seem to be natural candidates for investigation. Of particular import are consumer cognitive styles (Goldstein and Blackman 1978).

Consider, for illustration, the particular cognitive style of cognitive differentiation. Differentiation refers to the number of dimensions used by an individual in processing information (Bieri 1971). The more cognitively complex individual is assumed to have available a greater number of dimensions with which to construe his environment. Thus, in the context of multidimensional scaling, it is reasonable to expect that for the cognitively complex individuals, a higher dimensionality space would be required to adequately represent their perceptions. As individuals with high cognitive complexity form their percep-

tions in complex ways, a greater percentage of data (in the context of incomplete data) may be required to capture their perceptions and preferences. Likewise, the decision rules used by individuals are also likely to vary depending upon the cognitive complexity level. In similar vein, a number of other interesting hypotheses may be generated. Thus, the need to incorporate individual differences in multidimensional scaling and conjoint analysis of consumer perceptions and preference is apparent, and, to date, largely unmet.

Session on Multiattribute Scaling Models

Two of the three papers in this session deal with some of the issues which have been raised in the foregoing discussion. The paper by Green and DeSarbo describes and applies two models for representing unconstrained choice data in a multidimensional space. Acito and Olshavsky examine the robustness of conjoint analysis with respect to the levels per attribute used to construct the stimuli set. A protocol analysis of the decision rules employed by the respondents is also conducted. Leigh, Mackay and Summers examine the robustness of conjoint analysis with respect to the percentage of missing data and measurement scale for the dependent variable.

TWO MODELS FOR REPRESENTING UNRESTRICTED CHOICE DATA

Paul E. Green, University of Pennsylvania
Wayne S. DeSarbo, Bell Laboratories

Abstract

The collection of unconstrained choice data (in which respondents choose products, TV shows, etc. from a reference set that is left unspecified) is a common practice in marketing research. This paper describes and applies two models for representing such data as points in a multidimensional space. The models are illustrated in the context of preferences for sports cars.

In marketing research it is common practice to collect what may be called unrestricted choice data. By this is meant that respondents are neither instructed to choose a fixed number of alternatives nor is the set of possible alternatives explicitly listed. The interesting thing about this class of data is that ambiguity surrounds the alternatives not picked by a given respondent. One cannot tell whether nonchosen alternatives are viewed less favorably than chosen ones because the respondent is not required to list all of the items considered in choosing those that are preferred.

Recently, Levine (1979) has described an interesting model for scaling such data that leads to a joint space representation of stimuli (items chosen) and respondents (choosers). This is carried out by means of an internal MDS (multidimensional scaling) analysis (Carroll 1972) in which the stimulus space is not specified beforehand. Levine also mentions--but does not attempt to develop--a companion external analysis in which the stimulus space is prespecified.

The purpose of the present research note is twofold. We first show how Levine's technique can be applied to problems arising in marketing research. Second, we describe how his method can be adapted to external analysis problems, based on the inclusion of prespecified attribute ratings data and application of Carroll and Chang's PREFMAP-2 model (1971). The net result of this extension is the development of a joint space consisting of three sets of points--stimuli, attributes of stimuli, and respondents' ideal points. An empirical application of the two models is presented, followed by a brief discussion of potential industry applications.

The Models

We start out by describing the Levine model and PREFMAP-2. Since detailed descriptions of each model appear in the references cited above, our discussion is brief.

The Levine Model

Basic input data to the Levine model consist of I respondents' choices of J stimuli (e.g. brands, political candidates) in terms of preference, endorsement, appropriateness, or any other construct of interest to the researcher. The J stimuli are defined as the set union of all I individuals' choices. The basic idea of the Levine model is motivated by the following argument. If one had available an a priori stimulus configuration (as in external MDS analysis), a natural procedure would be to compute any given respondent's ideal point as the centroid of the stimuli he/she picks. By the same token, if an a priori respondent configuration were available one could position a stimulus point at the centroid of the points representing all respondents who happened to pick that stimulus.

What Levine's model does is to find two sets of coordinates, one set for respondents and one set for stimuli, that satisfy the centroid criterion. In Levine's notation, given respondents $1, 2, \dots, i, \dots, I$ and stimuli $1, 2, \dots, j, \dots, J$, let E denote a symmetric $(I+J) \times (I+J)$ matrix in which the entries are

$$e_{i, I+j} = e_{I+j, i} = 1 \quad (1)$$

if and only if respondent i picks stimulus j (with zero otherwise).

Next, let D denote an $(I+J) \times (I+J)$ diagonal matrix with general entry d_{kk} representing row sums of corresponding rows of E . Let \underline{x} denote a vector of $(I+J)$ coordinates corresponding to the I respondents and the J stimuli. The vector \underline{x} is a solution to the problem if for all x_k in \underline{x} , the entry x_k is proportional to the centroid of coordinates representing entities to which k is linked by virtue of either choosing or having been chosen. In scalar notation, the solution is:

$$\lambda x_k = \left[\begin{array}{c} d_{kk}^{-1} \\ \sum_{n=1}^{I+J} e_{kn} x_n \end{array} \right] \quad (2)$$

where $1 \leq k \leq (I+J)$ and $\lambda > 0$. Expressing (2) in matrix notation, we have:

$$\lambda \underline{x} = (D^{-1} E) \underline{x} \quad (3)$$

and, hence, the desired coordinates are the eigenvectors of the nonsymmetric matrix $D^{-1}E$. Various ways are available to expand $D^{-1}E$ to a symmetric form that permits standard eigenstructure computer routines to be used in solving for \underline{x} . As in any kind of eigenstructure decomposition, the researcher may wish to retain only the first few eigenvectors, accounting for the greatest proportion of the trace of $D^{-1}E$.

In sum, the Levine model takes an $(I+J) \times (I+J)$ matrix of 0-1 entries and solves for a set of coordinates \underline{x}_r in some $(I+J) \times r$ -dimensional space, according to the criterion of equation (2).

PREFMAP-2

Carroll and Chang's PREFMAP-2 algorithm was motivated by the desire to define a stimulus configuration from preference-like data alone. In PREFMAP-2 the preferences are typically interval-scaled (e.g. ratings), not 0-1 data. The key idea of the PREFMAP-2 model is to allow the preference data to be used twice. For example, if I respondents are asked to rate J stimuli with respect to preference, then it can be shown that a singular value decomposition of the doubly centered $I \times J$ matrix (i.e. the $I \times J$ matrix with both row and column means removed) yields both a stimulus space and a set of ideal points for respondents. Unfortunately, however, each is defined only up to a linear transformation. PREFMAP-2 finds the desired linear transformation of the stimulus space (which satisfies an explicit least squares criterion) so that the stimulus configuration is appropriately linked to the ideal point configuration.

Having found this linear transformation, the specific ideal point locations are found by quadratic regression in exactly the same manner used in the original PREFMAP algorithm. Somewhat more formally, let:

$$p_{ij} \approx a_i d_{ij}^2 + c_i \quad (4)$$

denote the preference scale value of respondent i for stimulus j ; d_{ij}^2 is the squared Euclidean distance between stimulus j and ideal point i ; a_i and c_i are parameters of a linear function for respondent i ; \approx denotes least squares approximation.

In PREFMAP-2, equation (4) is constrained to $a_1 = a_2 = \dots = a_I = a$, so that all respondents have the same slope coefficient. The first step in the computational procedure is to factor P , the preference data matrix with general entry p_{ij} , into the matrix product:

$$P \approx YX' \quad (5)$$

where X is the desired stimulus matrix, defined up to a linear transformation. The object is then to find that linear transformation T , so that:

$$X = X^*T. \quad (6)$$

PREFMAP-2 provides a least squares criterion that solves for T in the sense of best fitting (in a least squares sense) the preference values. Details can be found in Carroll and Chang (1971).

Comparing the Two Models

PREFMAP-2 and the Levine model were developed independently for different types of data--0-1 responses in the case of the Levine model and interval- (or ratio-) scaled data in the case of PREFMAP-2. What is proposed here is to use PREFMAP-2 in developing a joint space of stimuli and a third set of entities--attributes of the stimuli. In this case the list of attributes is prespecified. It is further assumed that the respondents represent a homogeneous sample with regard to their perceptions of the stimuli that they associate with specified attributes.

Having found a joint space of stimuli and attributes, each respondent's unconstrained stimulus choices (i.e. Levine-type pick k/n data) are used to compute that person's ideal point in the joint space of stimuli and attributes. Ideal points are computed as centroids of the stimuli that each respondent picks. This step leads to three sets of points in a common space--attributes, stimuli and ideal points. An attractive property of the approach is that, if all distances are comparable, one can consider ideal point to attribute distances. These latter distances can be substantively interpreted as the desirability that each respondent has for each stimulus attribute (as inferred from consideration of the respondent to stimulus associations and the stimulus to attribute associations).

In sum, we address the problem of modeling pick k/n data for the case of an externally supplied stimulus configuration (as mentioned by Levine). This is accomplished by the PREFMAP-2 procedure. We then apply the centroid feature of Levine's approach to modify PREFMAP-2, so as to include ideal points derived from 0-1 preference responses.

A Pilot Application

The two-stage approach, just described, was applied, on a pilot basis, to a set of data obtained from 35 respondents, drawn from a university population. Each respondent was asked to complete three tasks in the order shown:

1. List all foreign sports cars that come to mind that he/she would like to own, if money were not a major

- constraint. (No specified number or list of choices was provided.)
2. For each chosen car, pick as few or as many attributes as desired, from a specified list of 20 (see Table 1), that are most highly associated with the choice.
3. List three car attributes from the list of 20 that he/she would most like to have in a foreign sports car.

Table 1 shows the nine foreign sports cars whose names appeared most frequently across the set of 35 respondents.

TABLE 1
SPORTS CAR NAMES MENTIONED MOST FREQUENTLY
AND PRESPECIFIED CAR ATTRIBUTES

Sports Cars	BMW	Jaguar SJ6
	Datsun 280ZX	Mercedes 450SL
	Ferrari	MGB
	Fiat	Porsche
		Triumph
Attributes		
Economical to maintain		Plush interior
High acceleration		High reliability
High braking ability		Excellent cornering
Good for city driving		Sleek, racy lines
Easy-to-get parts		Conservative styling
Good gas mileage		Well engineered
High durability		Good service facilities
Beautiful lines		nearby
High resale value		Luxurious styling
Comfortable on long trips		Not temperamental
		Prestigious

Application of the Levine Model

Let us consider the Levine model first. In this case we focus only on the 35x9 matrix of 0-1 entries in which a 1 denotes stimulus j being picked by respondent i ; 0 denotes otherwise. (As described earlier, this matrix is then transformed to a 44x44 symmetric E matrix.) A computer program was prepared to solve for the respondent and stimulus matrix of coordinates, as described in equation (3).

The first 3 eigenvalues accounted for 55 percent of the trace. For illustrative purposes, Figure 1 shows a plot of dimensions 2 and 3.¹ Each eigenvector has been scaled by the square root of its associated eigenvalue. The horizontal axis might be described as a "value" axis that separates cars of lower price (e.g. MGB) from those of higher price (e.g. BMW). The vertical axis might be considered as an appearance axis that separates highly elegant cars such as Ferrari and Jaguar SJ6 from the more functional cars, like BMW and Porsche. (However, these interpretations are speculative, at best.)

Although omitted (for clarity) from Figure 1, the ideal points obtained from the Levine internal analysis showed a fairly high concentration around Mercedes, BMW, and Porsche; still, each car had one or more respondents for whom it represented the closest point.

The Two-Stage Analysis

The next step in the analysis was to apply the PREFMAP-2 model to the 9x20 matrix of associations data in which each cell entry denotes the frequency, across respondents, with which each attribute (column) is perceived to be associated with each sports car (row). Solutions, involving the fitting of the simple ideal point model to the

¹In eigenstructure solutions of the particular matrix product in equation (3), the first eigenvector is always a constant vector, and hence, is deleted in the spatial plots.

the optimally rotated and differentially stretched stimulus space, were obtained in both three and two dimensions. For illustrative purposes we comment only on the two-dimensional solution.²

All multiple correlations between the dependent variable (frequency with which each attribute was associated with a given sports car) and the stimulus coordinates of the attributes were significant at the 0.05 level or better. Figure 2 shows the joint space of sports cars and attributes.

Comparison of the sports car positions in Figure 1 and 2 shows the influence of the attribute-sports car associations on the placement of the sports car points.³ As noted, Mercedes, BMW, and Porsche are still relatively near each other (as are Jaguar and Ferrari) but Fiat and MGB are much more distant from each other in Figure 2 than in Figure 1.⁴

We note that such attributes are prestigious, sleek and racy, plush interior, beautiful lines, and comfortable describe the Ferrari and Jaguar, while the Porsche is described as having high resale value, good braking, high acceleration, good cornering and being well engineered.

Computing the Ideal Points

Respondent ideal points were next found, for the analysis summarized in Figure 2, by simply computing the centroid of all sports cars that each respondent picked. As a type of simple model validation, the next step in the analysis was to compute, for each respondent in turn, the average Euclidean distance of the three attributes that were picked as most highly desirable from his/her ideal point. This average was then compared to the average Euclidean distance of the 17 attributes that were not picked by that respondent.

Our hypothesis, of course, is that picked attributes will be closer, on the average, to a person's ideal point than those not picked. For 24 of the 35 respondents this was, in fact, the case. A sign test indicated that the result was significant beyond the 0.05 level. Hence, there is some evidence to support the reasonableness of the two-stage modeling approach proposed in this paper.

Potential Applications

As mentioned earlier, marketing research surveys abound with questions dealing with the choice of unconstrained options. For example, such data as top-of-mind brand recall (list those brands that you recall having tried at least once in the past six months), non-aided listings of product use occasions, free associations data, and reasons for liking (disliking) a new product concept lend themselves

²The root-mean-square fit across all nine sports cars was 0.76 for the two-dimensional solution and 0.83 for the three-dimensional case.

³In future studies the researcher may wish to rotate (or otherwise transform) the two solutions to maximal congruence via Cliff's (1966) algorithm or some other such procedure. Here, our interest was primarily to examine the character of the solutions just as they appeared in their respective computer printouts.

⁴Still, the canonical correlation between the sports car coordinates in Figure 1 and their counterparts in Figure 2 turned out to be 0.84, showing reasonably good correspondence between the two solutions.

well to analysis by the original Levine model.

Moreover, if respondents can be meaningfully classified on some type of a priori basis (e.g. favorite brand, heavy versus light product usage), additional analyses can be carried out to see if their ideal points occupy different regions of the joint space.

The two-stage approach, incorporating PREFMAP-2, followed by Levine-type external analysis (computing the centroid of picked items), is also applicable to a number of situations. For example, the stimuli could be print advertisements and the attributes could be characteristics of the ads--type of theme, believability of claims, copy points, etc. In other cases the stimuli could be political candidates and the attributes could be issues on which the various candidates are perceived to have a position. In still other cases the stimuli could be vendors of telecommunications services and the attributes could be various features of those services, such as excellent technical support, high equipment reliability, and so on.⁵

In short, it is not difficult to think of many classes of marketing problems for which the models described here may be applicable. It is hoped that additional empirical work will be carried out in the future regarding the pragmatic value of these models in consumer and industrial buyer research. Some initial research on the applicability of the Levine model has already been carried out by Holbrook, Moore, and Winer (1980).

JOINT-SPACE CONFIGURATION FROM PREFMAP-2

LIMITS TO ACCURACY IN CONJOINT ANALYSIS

Franklin Acito, Indiana University
Richard W. Olshavsky, Indiana University

Abstract

The relative performance of two conjoint designs, one using two levels per attribute, and the other using three levels is compared. Although the three-level design can potentially provide more information to the researcher, the increased difficulty of the evaluation task results in poorer data than obtained in the two level design.

Introduction

Conjoint analysis, beginning with the expository article by Green and Rao (1971), has developed into a mainstream tool of the market researcher. Investigations of the reliability and validity of the technique (e.g., Green and Wind 1973, Acito 1977, Scott and Wright 1976, and McCullough and Best 1979) have produced generally favorable evaluations. Researchers, however, still face difficult design decisions in using conjoint analysis for which the existing literature provides little guidance. An example of such a design issue is the number of levels per attribute. Experimental designs (see Addelman 1962) exist for two, three, four or more levels per factor. In some cases the number of levels is dictated by the context of the problem. In other situations, the analyst has control over the number of levels.

Price is one attribute which allows flexibility in selecting number of levels. Two levels, P_A and P_B , can be used to derive utility values U_A and U_B . Utilities for intermediate price levels can be obtained by linear interpolation,

$$U_I = U_A + \frac{P_I - P_A}{P_B - P_A} \times (U_B - U_A). \quad (1)$$

The analyst may not be willing to make such an assumption of linearity, however. To investigate non-linear effects, a third price level can be included in the design. Inclusion of the third level provides, in principle, at least, more detailed estimation of the utility function. However, two issues arise in increasing the number of levels per attribute which may result in poorer information from the conjoint analysis.

First, increasing the number of levels results in a greater number of parameters to be estimated, increasing the chances for statistical error with a fixed number of profiles or assemblies. (This is true only if the attribute levels are treated as discrete, which would be the case if the analyst did not wish to restrict the utilities to an a priori functional form.) Second, the additional information processing burden on the respondent can cause confusion, carelessness, or the adoption of simplifying choice heuristics frustrating the researcher's attempt to obtain greater accuracy. This study is designed to determine if a reduction in accuracy does in fact occur as the number of levels is increased. This study is also designed to provide information, through the simultaneous use of a process tracing technique (protocol analysis), concerning the hypothesized deterioration in the subject's capacity to cope with the increased information processing burden.

Method

Subjects

Twenty MBA students served as subjects in this study. They were selectively recruited on the basis of their ownership

or usage of a product (typewriters) which was of interest in another, unrelated, part of the study. Since subjects were randomly assigned to the 2 level or 3 level condition, the lack of control for prior knowledge of stereo receivers should not be a problem. Subjects were paid for participation. The small sample size is typical of studies in which protocol analysis is performed.

Stimulus Materials

Stereo Hi-Fi receiver was selected as a product of interest to students for which the number of levels per attribute could be varied uniformly (i.e., most major attributes were inherently multi-level).

For this study, six attributes and three levels were selected: Power Output (45, 30, 50 percent); Sensitivity (2.0, 2.5, 3.0 microvolts); Signal to Noise Ratio (75, 70, 65 decibels); Price (200, 250, 300 dollars); Warranty (3, 2, 1 years). The number of levels per attribute was either 2 or 3, depending upon the condition (underlined values were used in the 2 value condition). Using an orthogonal array design, 23 profiles were developed for each of the two conditions (Addelman 1962, Plackett and Burman 1946).¹ The letters "A" to "W" were used to indicate alternatives of the 2 level condition, while the numbers "1" to "23" were used to designate the alternatives of the 3 level condition.

A second set of eight holdout profiles was developed (completely different from those in the previous sets) involving only 2 levels per attribute, also based upon an orthogonal array. (The fact that this set had only 2 levels is not a critical issue; all that was desired was a criterion set of preference ranks.) These were numbered "100" through "800."

A third set of ten actual stereo receivers was developed by selecting a representative set of ten "actual" models from a stereo catalog. For this set, actual brand names were used and warranty was dropped since no warranty information was provided in the catalog. (Subjects were told to assume that all models had the same two year warranty.) Additional descriptive information was also available, as was a photograph of each receiver.

Procedure

The experimental task required respondents to express preferences for the alternative receiver profiles. These profiles were printed on 3" x 5" cards with each card listing the value of each of the six attributes. In the actual brand condition, pages from the catalog of a local stereo equipment retailer were used. To ensure comprehension of all attributes, definitions were presented to each subject on a separate sheet; subjects were requested to read these definitions and to refer to them throughout the choice process as needed.

The 23 cards for the first task were shuffled (for each subject) and arranged in an array on a table. Ten subjects

¹The orthogonal design for the three level case given by Addelman (1962) contained 25 assemblies; however, only 23 were distinct. The design for 24 assemblies given by Plackett and Burman for two levels has 22 distinct combinations. Twenty-three were used, so that one duplicate was included in this design.

were randomly assigned to the 2 level condition and ten to the 3 level condition. The subjects were asked to examine the "receivers" and to select the one model from the set of alternatives offered that would be purchased. Subjects were further instructed that they could not move or in any other way manipulate the cards. This was done to simulate the situation encountered in a retail outlet in which customers could not physically rearrange the alternatives.² Finally, subjects were instructed to verbalize all of their thoughts as the receivers were considered. The experimenter, who was seated opposite the subject, constantly monitored the protocol and reminded (in simple, nondirective ways) the subject to articulate his/her thoughts whenever necessary to increase the amount of protocol data.³ Each session was tape recorded with the subject's knowledge.

After the subject made the first choice from the 23, that alternative was eliminated and he/she was asked to imagine it were no longer available for sale. The subject was instructed to again make a "purchase" decision from the remaining alternatives. This procedure was repeated until a preference ordering for all 23 alternatives was obtained.

To provide the data needed to test the predictive ability of conjoint analysis, subjects were asked to express their preferences for the set of eight holdout profiles with the same procedure used for the 23 alternative set. Finally, subjects were asked to indicate rank preferences for 10 models of receivers from the catalog pages. Data for each subject were submitted to MONANOVA (Kruskal 1965) to derive part-worth utility values.

Results

Prediction of "Holdout" Ranks

The ranks of the eight holdout profiles were predicted using the utility values derived from the conjoint analysis and the Spearman rank correlation coefficients were computed between the predicted and actual ranks for each respondent. Table 1 shows the mean correlations for the two and three level designs. The difference in the means was not significant. Moreover, the two level design produced more direct "hits" on the ranks than did the three level design (45 out of a possible 80 versus 31 out of 80). A χ^2 test for the 2 x 2 table resulting from this data indicated a significant difference at the .05 level.

Prediction of Actual Brands

The respondents' ranks for the ten actual brands were disaggregated according to the three brands used in the experiment. Three models each of Pioneer and Kenwood receivers were used while four models of the Technics brand were used. Appropriate utility values derived from the conjoint analysis were combined (using linear interpolations where necessary) to predict the preference ranks for each of the three sets of ranks. Table 1 shows the distribution of perfect prediction for each of the experimental conditions. The differences between the overall number of perfect predictions (24 out of 30 for the two level design versus 15 out of 30 for the three level design) was significant beyond the .05 level using a χ^2 test.

² Bettman (1979) has made a call for such realism in study design. Olshavsky and Acito (1979) have recently investigated the effects of changes in card sorting procedure on choice rule.

³ Evidence concerning the lack of interference of protocol analysis on cognitive tasks has been recently reviewed by Simon (1979).

Utility Value Violations

In many situations the directionality of respondent preferences for attribute levels can be stated a priori. In this experiment, each of the attributes had a clearly defined preference directionality (e.g., lower distortion should

TABLE 1

Violations of A Priori Attribute Utilities
for Extreme Values

Condition	Attribute					
	Power 45w>15w	Price \$200> \$300	Distortion .1%>.5%	Sensitivity 2.0µv> 3.0µv	Noise 75db> 65db	Warranty 3 yrs.> 1 yr.
2 levels	0	3	1	1	1	0
3 levels	1	3	1	7	6	0

be preferred to higher distortion, lower price preferred to higher price, etc., with the usual ceteris paribus assumption). For both experimental conditions, the number of violations of a priori expectations was determined. For the three level condition, only the outer extreme levels of each attribute were used for this assessment. Table 2 shows the results. A total of six violations was observed for the two level condition while 11 violations were observed for the three level condition. (If the price utility sign is not considered, the two level had three violations and the three level design had 8 violations)

The utility values for the intermediate levels of each attribute in the three level condition were also examined. For each attribute used in this study, it seemed appropriate to assume that the utility values for the intermediate levels should lie between those for the extremes. In other words, utility functions for each attribute were assumed to be monotonically related to levels of the attribute. A number of violations of this monotonicity were observed: two violations for the power attribute; four for price; two for distortion; seven for FM sensitivity; five for noise; and six for warranty.

Error Estimates

The two-level design required the estimation of six parameters with MONANOVA while the three level design required

the estimation of twelve parameters. Since the number of profiles was 23 for both designs, the 3 level design is more susceptible to error. One perspective on this problem is gained by examining the stress values expected for both designs using random data. The average stress for the two level design with random data was .72, with a standard deviation of .09. Assuming the stress values to be normally distributed, 5% of the stress values for random data are expected to be below 57%. A similar procedure for the three level design resulted in an estimate that 5% of the stress values for random data would be below 29%.

Table 1 shows the average stress values observed for the two level and three designs. Since the random data results above indicate that it is "easier" to achieve a low stress value with the three level design, lower stress values would be expected for real data using that design. The averages indicate that, to the contrary, the stress for the two level design was somewhat lower, although the difference between the two designs was not significant at the .05 level.

Choice Rule Analysis

The protocol analysis was based on transcripts of the tape recordings for the set of 23 profiles only. The objective was to ascertain the decision rule used by each subject. The tape recorded protocols were transcribed and then broken down into a sequence of task relevant statements as is typically done with protocol data (Payne, Braunstein, and Carroll 1978). Subjects were then classified according to the type of choice rule they used (as inferred from the protocols). In the interest of consistency and to ensure reliable categorization, the same definitions of choice rule and coding criteria used by previous researchers were adopted (Olshavsky 1979, Payne 1976, Wright and Barbour 1977).⁴

Of the 10 subjects in the "two-level" condition, five used a lexicographic choice rule (by attribute). Three used a conjunctive rule (by brand) but modified the importance of the choice criteria according to a specific attribute priority order. And two used a modified conjunctive rule where priority of attribute was varied after all alternatives with the most desired attribute were depleted.

Of the 10 subjects in the three level condition, seven used a choice strategy that was so inconsistent and ambiguous that it was not possible to classify it as a single choice rule or even a combination of choice rules. In those seven cases a pair-wise comparison process (attribute dominance or additive difference) was used with little or no attempt to apply the pair-wise comparison strategy to all remaining alternatives. Of the remaining three subjects, one used a lexicographic rule but then switched to a pair-wise (attribute dominance) strategy.

Discussion

The major finding of this study is that increasing the number of levels per attribute does not necessarily increase accuracy in utility function estimation. The results suggest that, to the contrary, the utility values derived from the two level condition are somewhat superior in predictive ability when used in the manner described. This superiority persists even in cases where interpolations of utility values are needed (as in the catalog descriptions). If the three level design were superior, its superiority should be evident where interpolated utility values were used, since non-linearities in the utility functions would be captured. The utility values derived for the three level condition also were more likely to violate a priori assumptions about

⁴Details of the procedure for choice rule identification have been discussed in previous papers, e.g., Olshavsky and Acito 1980.

directionality of preferences. This result must of course be qualified given the small sample size and the unrepresentativeness of MBA students. Further research on this important issue is required using a larger sample of different types of subjects and less complex products.

These results could be due to the instability in parameter estimates resulting from fewer degrees of freedom remaining for error and/or they could be due to the confusion of the respondents. However, the error analysis performed here and the protocol analysis suggest that the more likely explanation is that most of the respondents in the three level condition were unable to cope with the increased information processing burden imposed upon them. This implies that great care must be given to the interpretation of conjoint analysis results based on designs involving a large number of levels per attribute.

Abstract

The rise in popularity of conjoint analysis as an approach to studying consumer preferences has been accompanied by the development of a variety of alternative methodological procedures. Interest in this paper is focused on the performance of "experimentally efficient" designs. Issues which face the researcher interested in deciding upon an appropriate design for conjoint analysis are discussed and results of a pilot study on the test-retest reliability and convergent validity of alternative procedures are presented. The results tend to favor the "less efficient" designs with full factorial and pair-comparisons data gathering procedures having the greater reliability and validity.

Introduction

Over the past decade, conjoint analysis has become an increasingly popular approach for the study of consumer preferences. In an excellent review of the literature, Green and Srinivasan (1978) have identified six major methodological steps involved in applying conjoint analysis: (1) selection of a model of preference; (2) data collection method; (3) stimulus set construction for the full profile method; (4) stimulus presentation; (5) measurement scale for the dependent variable; and (6) estimation method. The purpose of the paper is to investigate the effects of the methodological decisions in steps three and five on the reliability and validity of conjoint analysis.

Interest in this area is motivated by the recent emphasis on the use of "experimentally efficient" designs with conjoint measurement (Acito 1979, Green 1974, Green et al. 1978). Green and Srinivasan (1978) define an experimentally efficient design as one that returns a high amount of information per unit of experimental time. They suggest that efficient designs are likely to involve fractional factorials (stimulus set construction) and rank order (as opposed to pair-comparison) data (measurement scale). Of course, efficiency can also be used in a statistical sense to refer to estimates that have the property of minimum variance. By studying the reliability and validity of experimentally efficient designs, insight should be obtained as to whether experimentally efficient designs will lead to statistically efficient estimates of model parameters.

This issue is by no means trivial. Experimentally efficient designs reduce the amount of time required of a subject to provide preference data with respect to alternative product designs with a specific set of attributes. To the extent that reduction of subject time prevents fatigue, boredom, and stereotyped response patterns, random or error variance will be reduced and reliability and validity may be improved. However, the price of this savings in subject time is a reduction in the number of independent observations. Estimates of model parameters are thus more dependent on any given response. The self-compensating nature of random error has less opportunity to occur with a small number of observations and reliability and validity can be adversely affected. Experimental methods which are empirically shown to have higher reliability and validity have a better chance of providing statistically efficient estimates. However, experimentally efficient designs need not lead to increased reliability and validity.

The following sections expand upon the issues relevant to stimulus set construction, measurement scale, and reliability and validity. After this, a study in which the reliability and validity of 13 different conjoint measurement procedures based on combinations of stimulus sets and measurement scales is described. A presentation of the results and a discussion of the findings concludes the paper.

Stimulus Set Construction

The stimulus set construction step includes the issues of attribute range and variation, interattribute correlation, and full versus fractional factorial designs. Only the last issue is considered here. For full factorials, the number of responses required of a subject increases geometrically with the number of attributes. Even with a relatively small number of attributes, full factorial designs can become infeasible.

Even when the number of required responses for a full factorial design appears feasible to use with a given measurement scale (e.g., 5 attributes at 2 levels each; 32 stimuli) one might still find that a fractional factorial design produces more reliable and valid results than a full factorial design. The reduction of the subject's task with a fractional factorial may tend to increase the study's response rate and encourage respondents to put more time and effort into evaluating each individual stimulus. Conversely, the smaller number of responses provides less opportunity for random errors to cancel each other. Statistically, the basic issue is whether the lower degrees of freedom in a fractional factorial design are compensated for by higher quality (lower error) data. This is, of course, an empirical question and depends upon the particular stimuli being investigated, the subjects who participate, and the research setting. Caution is thus advised in generalizing the results from one study to another.

Another potential problem with fractional factorial designs is that they do not allow for the estimation of some higher order interaction effects. However, these will frequently be negligible and estimation of lower order effects may be sufficient.

Measurement Scale for the Dependent Variable

A variety of procedures for "defining a measurement scale for the dependent variable" have been used. Coombs (1966) refers to these as "methods of collecting data." The procedures fall into two basic categories, nonmetric (e.g., rank order and pair-comparisons) and metric (e.g., rating scales, graded pair-comparisons, and constant sum pair-comparisons). The nonmetric procedures only require the subject to make ordinal judgments concerning their preferences (or purchase intentions) while the metric approaches involve at least interval scale responses. The choice between these two basic approaches involves the experimental questions of whether subjects can provide metric responses and whether the longer time periods that usually accompany the greater number of responses frequently required with some nonmetric methods (e.g., pair-comparisons) result in boredom, fatigue and greater random error.

Of the two nonmetric approaches, rank order has been most

popular for collecting preference data for conjoint analysis (e.g., Green and Wind 1975; McCullough and Best 1979). This method generally requires less respondent time than pair-comparisons and, for a large number of stimuli, the pair-comparisons method becomes impractical. At a given level of fractionation, the number of responses required for pair-comparisons may greatly exceed that required with rank orders. Thus, a half factorial design for five attributes of two levels each would, for pair-comparisons, involve 120 comparative responses ($2^{5-1} = 16$; $C(16,2) = 120$), and for rank orders, it would involve 16 responses. Corresponding values for a full factorial design are 496 and 32 responses respectively. Unfortunately, when using the pair-comparisons method, incomplete block designs (Green 1974) often do not allow for the development of a complete rank order of the stimulus set for individual subjects (Cliff 1975).

Among the metric approaches, rating scales are the easiest to apply. Unlike the nonmetric methods of rank order and pair-comparisons, rating scales do not force a subject to use "comparative" judgments since the stimuli are evaluated individually, one at a time. This contributes to the anchoring effect difficulties that the method experiences. However, use of warmup trials and familiarization periods where the subject reviews all stimuli before making the rating responses can lessen the severity of this problem.

Graded pair-comparisons are a metric procedure that, because of its explicit requirement of comparative evaluation, would appear to have an advantage over rating scales with respect to potential anchoring effects. Its advantage over (binary) pair-comparisons is that it allows the respondent to specify a degree of preference for one stimulus over another. Another advantage over pair-comparisons is that graded pair-comparisons can use both fractional factorials and incomplete block designs to determine respectively the construction and selection of the stimuli that are presented to the subject.

Constant sum pair-comparisons, the third metric procedure, require ratio scaled responses and would seem to share some of the problems and advantages associated with graded pair-comparisons. The nature of the stimuli and familiarity of the subjects with the stimuli are important factors in deciding whether ratio scale responses are reasonable to require.

Reliability and Validity

Reliability can be conceptualized as consisting of temporal and structural components (McCullough and Best 1979). The focus of this paper is on temporal stability which is concerned with the effect of random (error) variance. Test-retest methods are a common way of measuring the temporal stability of consumers' responses. When fractional factorial designs are used, alternative forms should be used on the test and retest portions to reduce the possibility of memory producing a high test-retest correlation. This is of particular importance when the time interval between test and retest is of short duration. Product moment correlations are usually used to measure the similarity of test and retest (e.g., Acito 1977, Green and Srinivasan 1978) though other measures, such as sums of squared differences, are also appropriate. Correlations may be computed among the independent part-worths or among the estimated utilities that are derived from the part-worths. Most studies have employed the latter approach (e.g., Acito 1977, Green et al. 1972, Jain et al. 1975). Acito (1979) argues that the relatively small number of observations available when comparing the test and retest part-worths will lead to unstable results. However, it should be noted that the higher degrees of freedom associated with utility values is partially illusory since these values are functionally related through the part-worths. A design with five attributes at two levels each, for example, produces at most five "independent" part-

worths (four when the unit of measurement is arbitrary). Furthermore, if the variance of the part-worths is small (i.e., the attributes are all of relatively equal importance), the test and retest part-worths could be quite close (in an absolute sense) yet yield a low correlation. The severity of this problem can be tested by either comparing the test-retest correlations to the within test variance of the part-worths or by using a different measure of test-retest association, such as the sum of squared differences.

Validity considerations necessarily depend on the use for which the measure of interest is intended. Conjoint analysis of preference judgments has been frequently proposed as a procedure for "predicting" the success of potential new products (Green and Srinivasan 1978, Pekelman and Sen 1979). As such, predictive validity with actual choice behavior as the criterion would be of central interest (Wittink and Montgomery 1979). For many non-commercial research studies this is economically infeasible and a less demanding measure of future choice behavior, such as a raffle where subjects identify the product they would select if they were to win could be used to provide a measure of predictive validity. Alternatively, the researcher can obtain a second measure of preference or intentions to provide a measure of convergent rather than predictive validity (Scott and Wright 1976, Cattin and Weinberger 1979).

A number of articles have dealt with the reliability and validity of conjoint analysis. A review of these efforts has recently been provided by McCullough and Best (1979). Much of this work has dealt with the reliability and validity of alternative algorithms and/or individual conjoint measurement approaches. The comparative reliability and validity of experimentally efficient designs have generally been ignored.

Methodology

A convenience sample of 52 undergraduate students in an introductory marketing class was used in this pilot study. The stimuli were written descriptions of inexpensive pocket cameras. Pocket cameras were selected because they represent a moderately complex product category of reasonably high interest to the respondent population. An article on comparative ratings of pocket cameras in a consumer magazine was consulted in choosing the five camera attributes that were used in the study: (1) fixed versus zone focus, (2) maximum aperture--large versus small; (3) automatic exposure--"yes" or "no;" (4) electronic flash--"yes" or "no;" and (5) built-in telephoto--"yes" or "no." Many commercial applications consider a larger number of attributes and attribute levels. However, it was necessary to limit the number of attributes used in this study to insure that the less efficient procedures would be feasible for most of the stimulus sets considered. Five "measurement scales for the dependent variables," two nonmetric methods (rank order and pair-comparisons) and three metric methods (graded pair-comparisons, direct subjective estimates of the dollar values, and rating scales) were used.

The rank order instructions were patterned after those presented in Green and Wind (1973, pp. 261-62). Respondents in the pair-comparisons condition were merely asked to check the camera description (within each pair) they most preferred. For graded paired comparisons, respondents were also asked to specify (for each pair of stimuli) how much more they would be willing to pay for the camera of their choice. The "direct subjective estimates of the dollar value" of the cameras represented the "maximum the respondent was willing to pay (in dollars) for each of the cameras." Finally, the rating scale procedure involved evaluating each camera on an 11-point scale from "least prefer" to "most prefer."

Implementation of the above would suggest 15 approaches (3 levels of fractionation and 5 methods) to collecting preference data. However, two of these (combinations of the full factorial stimulus sets with pair-comparisons and graded pair-comparisons) were not deemed feasible because of the large number of responses required ($C(32,2) = 496$). These treatment combinations were thus excluded. Even with the 1/2 fractional factorial, 120 ($C(16,2)$) responses are required for both the graded and "ungraded" pair-comparisons. Because of the subject's added task of evaluating the degree of differential preference under the graded pair-comparisons method, 120 responses were considered infeasible for this method. Hence a partially balanced incomplete block design was utilized with the 1/2 fractional factorial for graded pair-comparisons. This was possible because of the interval scale nature of the data.

The 13 methodological treatments were randomly assigned to the 52 subjects (4 per cell). Each respondent was given a short statement explaining each of the five product attributes to eliminate potential problems with unfamiliarity concerning the terminology used. Following the completion of their respective preference judgment tasks each subject was asked to give a direct subjective estimate of the differential dollar value of the "higher" (versus the "lower") of the two levels for each attribute. This provided a second measure of each subject's part-worths. As such, it presented an opportunity to investigate the convergent validity of the part-worths. It also permitted the comparison of the test-retest reliability of the conjoint analysis procedures with that of a rather simple and less costly approach to analyzing consumer preferences.

After approximately one month the subjects repeated their respective tasks. The alternative form approach (i.e., a different set of stimulus descriptions) was not possible for the full factorial case and was not used for the fractional factorials to maintain consistency across treatments.

Analysis

Because of the small cell sizes and the relatively high variance within cells no statistical tests were performed. The results must be considered as only suggestive of the comparative viability of the alternative approaches. We will rely on examining trends in the data in interpreting the results.

Since most of the attributes were naturally dichotomous and all were represented at two levels, the "part-worth function" model was considered the most appropriate for representing the respondents' preferences. The more highly fractionated designs did not allow for the estimation of interaction effects and none were considered for any of the results presented in order to maintain comparability across data collection conditions. However, the existence of interaction effects was investigated for some of the metric models where possible (e.g., the rating scale used with a full factorial) and few (and in most cases none) were found to be significant for any of the subjects.

Monotone analysis of variance (Kruskal 1965) was used to estimate the part-worths for the nonmetric method (i.e., rank order and pair-comparisons). To convert the pair-comparisons into the predominant rank orders required by the MONANOVA algorithm, TRICON (Carmone et al. 1968) was used. Other procedures for the conversion of pair-comparisons to predominant rank orders are possible (Carroll 1972) but use of alternative conversion methods makes little difference.

Least squares estimators were used to derive the part-worths for the metric methods (i.e., graded pair-

comparisons, direct subjective estimates and rating scales). For the graded pair-comparisons data, each observation was classified by the differences in the first order parameters of the paired stimuli (see Dykstra 1958 for a discussion of the analysis of graded pair-comparisons data).

Pre-Analysis of the Data

The resultant part-worths were examined for a priori directionality and pareto optimality violations. In this study there appeared to be strong rationale for assuming that one level of each attribute should be preferred (e.g., a large aperture should be preferred to a small aperture). For other products and/or attributes such an assumption may not be warranted. However, whether or not this assumption can be made in a particular situation should not affect the comparative reliabilities of the various conjoint measurement approaches. Six subjects had multiple directionality violations on at least one of the "tests." The number of possible pareto optimality violations was also calculated for each task. Seven subjects were eliminated from the study because their data exhibited 15% or more of all possible pareto optimality violations. Five of these subjects were among the six having multiple directionality violations.

Test-Retest Reliability

Because of the small cell sizes and substantial within cell variance, the test-retest reliability results must be viewed as primarily suggestive rather than conclusive. Two measures of reliability were considered: (1) within subjects test-retest correlations of part-worths; and (2) within subjects test-retest correlations of the estimated utilities. Both the average adjusted (for sample size) and unadjusted correlations are presented in Table 1.

The average utility correlations were uniformly high (ranging from .799 to .988 "unadjusted" and from .791 to .988 "adjusted") while the average part-worth correlations varied widely across the data collection conditions (ranging from .074 to .924 "unadjusted" and from .000 to .879 "adjusted"). Similar results for utility correlations have been reported in the literature (Acito 1977, Green et al. 1972, McCullough and Best 1979). Over all conditions, the average stimulus value (utility) correlation exceeded the average for part-worths by more than .4 (for both "adjusted" and "unadjusted"). A relatively high test-retest stimulus value correlation does not necessarily suggest a substantial test-retest part-worth correlation. For example, the average adjusted test-retest stimulus value correlation for the subjective estimate (1/2 fractional factorial) condition was .885, while the corresponding average part-worth correlation was .000. The correlation between the two sets of reliability measures (stimulus value and part-worth) was only .479 (for the adjusted test-retest correlations).

Adjusting for sample size would seem particularly important for part-worth correlations since they typically involve small "sample" (number of part-worths) and the unadjusted correlations tend to be low to moderate. This results in a significant attenuation of the correlations. In the present study, the overall average part-worth correlation was reduced by .105 (from .490 to .385) compared with only .004 (.895 to .891) for the stimulus values.

The test-retest part-worth correlations would seem to be considerably more relevant than the stimulus value correlations in evaluating the reliability of conjoint analysis procedures. The primary objective of these procedures is to provide reasonably accurate estimates of these parameters. The utility value correlations may be somewhat inflated in the sense that merely observing pareto optimality in making the preference judgments can produce fairly substantial values on this measure. Also,

TABLE 1

the fact that the utility values are linear functions of the part-worths will tend to make these correlations high. Much the same argument could be made concerning rank order correlations between respondents' test and retest preference judgments which serve as the input for conjoint analysis.

Earlier it was argued that if the variance of an individual's part-worths was small, one might expect his test-retest reliability to be low. If the argument holds in this situation, one would expect that the correlation of the individual part-worth reliability measures with the "within subject" variances of the part-worths would be positive. This correlation was calculated across all subjects in two ways, using the average of the test and retest variances of the part-worths and using the minimum of the test and retest part-worth variances. The respective correlations were 0.10 and 0.11. While the above argument is intuitively plausible, it did not find substantial support in this study.

In comparing the results for the alternative approaches one notices that only small differences exist with respect to average test-retest stimulus value correlations, suggesting the lack of sensitivity of this measure. However,

the part-worth correlations display substantial variability. With the exception of the subjective estimate method, the less fractionated designs (full and half factorials) tend to produce more reliable part-worth estimates. Apparently, in this particular research context, the control over random error provided by the larger effective "sample sizes" of these designs more than offset any tendency for the increased effort demanded from the respondent to produce less stable judgments concerning individual stimuli.

Those methods involving "comparative" judgments (i.e., pair-comparisons, graded pair-comparisons, and rank order) tended to perform better than those requiring "individual" judgments (i.e., subjective estimate and rating scale). Graded pair-comparisons had the highest overall average test-retest part-worth correlation (.628) followed by paired comparisons (.615) and rank order (.315). Furthermore, the highest average correlation (.897) was obtained for the graded pair-comparisons (1/2 fractional factorial--incomplete block) design. Perhaps this method is more attractive, at least for situations involving a low to moderate number of attributes, than would be suggested from its limited use in previous marketing studies. However, in its present form, this approach may not be optimal for larger (sample size and number of attributes) commercial studies.

Convergent Validity

The direct dollar metric estimates of the part-worths were included in both the "test" and "retest" to provide a baseline for evaluating the test-retest reliabilities of the various conjoint analysis approaches and also for the purpose of examining convergent validity. These direct dollar metric estimates were obtained after the respondents provided their conjoint analysis data. Their reliability could be affected by fatigue or boredom created by the conjoint analysis tasks. However, this did not seem to be a significant problem. Except for the subjective estimate method, there was no systematic tendency for the less fractionated factorial designs (those requiring more judgments) to be associated with lower test-retest reliabilities for the direct dollar estimates of the part-worths (Table 2). Incidentally, the subjective estimate approach to conjoint analysis resulted in low test-retest reliabilities. It is not clear whether the respondents in this condition were unreliable per se or whether the difficulty of the subjective estimate task negatively affected these subjects' performances on the subsequent dollar metric task.

The direct dollar metric estimates of the part-worths demonstrated a higher average (over all conditions) test-retest reliability than the combined average obtained for the conjoint analysis approaches studied (.500 vs. .385) even though its reliability suffers from a lack of redundancy in the data collected. Furthermore, graded pair-comparisons which appears to share method variance with the direct dollar metric method was the only approach for which the test-retest reliability was higher for conjoint analysis than for the dollar metric given common subjects (.628 vs. .560). In this study at least, the less complex and time consuming task of providing direct dollar metric estimates of part-worths was superior (with respect to test-retest reliability) to most of the popular conjoint analysis approaches. While it could be argued that these direct estimates are more easily remembered, memory shouldn't be a significant factor in this study since the test and retest were separated by approximately one month and the subjects were unaware that a retest was to be conducted.

Convergent validity relates to the amount of agreement among maximally different methods of measuring the same construct. Our second method (the direct dollar metric estimate of the part-worths) like the conjoint analysis

TABLE 2

^aAll correlations have been adjusted for sample size.

procedures, relies on stated preferences, and as such, shares some method variance with these procedures. Hence, only a weak test of convergent validity was possible.

Each subject's dollar metric estimates were correlated with their conjoint analysis results for both the test and retest and the correlations averaged (Table 2). The results show that this measure of convergent validity tends to be higher for the less fractionated designs (i.e., full and half factorials). The methods involving comparative judgments (i.e., rank order, pair-comparisons, and graded pair-comparisons) fared better than those requiring "absolute" judgments. This was expected since these designs previously demonstrated higher test-retest reliability. Convergent validity (with the direct dollar metric estimates) for graded pair-comparisons was substantially higher than that obtained for any of the other methods. However, this is probably due in part to the method variance they share (i.e., the similarity of the measurement tasks).

Summary

In spite of the increasing popularity of conjoint analysis among marketers, only limited published evidence exists regarding its reliability and validity within the various research contexts in which it has been applied. While the superiority of conjoint analysis over "direct subjective estimates" of the "part-worths" appears to be widely

accepted, substantial empirical evidence for this position is lacking. Furthermore, those wishing to apply conjoint analysis in a specific decision context have little objective information on which to base their selection of a methodological approach from the many alternatives available.

If conjoint analysis is to be more than a passing fad researchers must establish its test-retest reliability and predictive validity over a broad range of consumer choice situations. Moreover, it needs to be demonstrated that this set of techniques provides more accurate predictions (forecasts) than those obtainable from merely asking respondents to directly report their "part-worths." It is not sufficient to merely compare conjoint analysis with naive models which utilize no information concerning the relative importance of the various attributes. Finally, there is a need for empirical studies focusing on the comparative viability of the alternative methodological approaches under a variety of research conditions.

The present study has centered on a systematic investigation of the effects of two aspects of conjoint analysis (the use of fractional factorials in stimulus set construction and "measurement scales for the dependent variable") on the test-retest reliability and convergent validity of the estimated part-worths. Since the cell sizes were small, only tentative conclusions concerning the relative effectiveness of the alternative methodological approaches are appropriate.

The results suggest that the less fractionated design tends to produce higher test-retest part-worth reliabilities when the number of dichotomous attributes is limited, although these designs will become less feasible as the number of attributes is increased. Those methods involving "comparative" judgments (i.e., pair-comparisons, graded pair-comparisons, and ranking) were more reliable than those requiring "individual" judgments (i.e., direct subjective estimates of the dollar value of the stimuli and rating scales). In the case of rating scales, this may well have been partially due to problems with anchoring effects.

When compared to the test-retest reliability of the direct subjective estimates (dollar metric) of the part-worths, the conjoint analysis results were disappointing. Only graded pair-comparisons appeared to be superior on this criterion. This approach also showed the highest convergent validity with the direct part-worth estimates.

In other research settings, particularly those with extensive stimulus sets, experimentally efficient designs may be more desirable if not necessary. While some may argue that our evaluation of conjoint analysis is unfair in that it considers only individual reliability and validity and does not consider the reliability of the "average" (aggregate) subject, it must be remembered that direct part-worth estimates will also improve when across subject averages are used. The reliability of averages will always improve as sample sizes increase. Furthermore, if individual reliability and validity is weak, the ability of conjoint analysis to explore individual differences and define market segments must be questioned.

MULTIATTRIBUTE CHOICE MODELS: A CRITICAL REVIEW

Jeffrey E. Danes, Virginia Polytechnic Institute and State University
Philippe Cattin, University of Connecticut

Abstract

This paper reviews and discusses the work by Green and Desarbo, "Two Models For Representing Unrestricted Choice Data," Leigh, Mackay, and Summers, "On Alternative Methods For Conjoint Analysis," and Acito and Olshavsky, "Limits To Accuracy in Conjoint Analysis."

Two Models For Representing Unrestricted Choice Data

Green and Desarbo's paper, "Two Models For Representing Choice Data," is one more advancement to be included in the rapid growth of multidimensional scaling models. Today market researchers may choose between a metric or non-metric algorithm, scale a 2-way matrix, a 3-way matrix, may employ longitudinal scaling, and may choose from a variety of metric axioms: Euclidean, Minkowski, as well as Riemannian (cf. Lindman & Caelli 1978, Piezko 1975). Further, market researchers have numerous data collection methods at their disposal. The Green and Desarbo paper makes an advance in this latter category. They first demonstrate the use of Levine's model (1979) for scaling unconstrained choice data--data obtained from respondents who are neither instructed to choose a fixed number of alternatives nor is the set of possible alternatives explicit. The primary contribution of the Green and Desarbo paper is the extension of Levine's (1979) model to unconstrained choice data in which the stimulus set is prespecified. The outcome of their effort is a multidimensional space that yields: ideal points, stimulus points, and attribute points. Although it is traditional to map attributes as vectors, the model provided by Green and Desarbo maps attributes as points in a multidimensional space. Let us focus our attention upon this feature.

Utility of Attributes As Points

One criticism of the Green and Desarbo paper is that they do not explain the role that dimensions play in their model. If attributes are represented as points, what do the dimensions represent?

It is now well known that the dimensions obtained in multidimensional scaling do not necessarily correspond to attributes. This has been found by numerous researchers who have regressed attribute vectors into multidimensional spaces. It is not uncommon to find six or more attribute vectors in a two or three dimensional space (cf., Schmidt 1976). The dimensions of a multidimensional space do not necessarily correspond to attributes; thus, it may be more meaningful to view the obtained dimensions as an arbitrary reference system in which points of all kinds are plotted. A common example of an arbitrary reference system in which dimensions have no inherent meaning is the letter-number grid on a city map. These dimensions may be translated and rotated with no harm done to the distance between any two homes. The coordinates simply tell us where "Oak Street" is relative to "Elm Street."

Green and Desarbo's treatment of the attribute as a point in space, however, gives new meaning and new potential applications of multidimensional scaling to market and consumer research. Let us now comment on one possible application of representing attributes as points.

Example Application: Advertising Strategy

The Green and Desarbo paper used association data for their example application. Hence, distance in the space is a function of association in the data--the highly associated points are close together. They also mapped ideal points. Without loss of generality, let us assume a homogeneous population with one ideal point, I; let it be mapped as follows (see Figure 1):

FIGURE 1

A Simple MDS Map With Attributes As Points

Let us denote the product as P, the ideal point as I, and three attributes as A_1 , A_2 and A_3 . Without changing the associations (or inter-distance relations), we may translate the dimensions of the space so that the product, P, has zero coordinates (see Figure 2).

FIGURE 2

Translated MDS Map With Attributes As Points

One marketing goal may be to "move" the product closer to the ideal point. How can this be accomplished?

Communication researchers have long known that messages that repetitively associate two objects (e.g., Watergate and political crime) result in increased perceived similarity between the two objects. Likewise, the same appears to

be true for objects and attributes (Barnett, Serota, and Taylor, 1976). Marketers capitalize on this principle when they associate their product with intuitively desirable attributes.

Let us assume that a marketer, through communication, associates their product, P, with A_3 . Let us also assume that the communication campaign is relatively lengthy. What is the likely outcome? If the campaign successfully teaches the association the product, P, should "move" closer to A_3 . Let us denote the "new" location as P' in Figure 3. However, this

FIGURE 3

New Location of Product After Association of Product, P, With Attribute, A_3

is not consistent with the original goal--moving the product closer to the ideal point. A campaign that associates the product, P, with say, A_2 should be a much better strategy. But, the resulting direction of motion is slightly off target. However, if we assume that vector averaging is a viable cognitive principle, then the two-attribute message in which the product, P, is associated with, A_2 and A_3 , would be even better. This principle is diagrammed in Figure 4.

FIGURE 4

New Location of Product After Association of Product, P, With Attributes, A_1 and A_2

Figure 4 pictures the "final state" for the product given an advertising campaign that is successful in teaching the new associations, i.e., the product, P, is associated with the two attributes, A_1 and A_2 . The example we present here, of course, is over simplified. However, generalizations to spaces of larger dimensionality with more attributes is possible. Extended models and algorithms for using attributes as points (in multidimensional spaces) for the

measurement of communication and marketing processes may be found in Woelfel and Danes (1980).

Summary

Green and Desarbo's work is one more contribution to the rapidly growing arsenal of multidimensional scaling techniques. They provide a multidimensional scaling model derived from Levine's (1979) earlier model development. The primary contribution of their work is the extension of Levine's (1979) model to unconstrained choice data in which the stimulus set is prespecified. The outcome of their effort is a multidimensional space that yields: ideal points, stimulus points, and attribute points. The role of the dimension, which is usually treated as an attribute, is not made clear by Green and Desarbo. Our discussion, however, suggests that the dimensions in a multidimensional space may be usefully viewed as an arbitrary reference system, which by themselves, have no inherent meaning. Our discussion then moved to potential applications of the new model presented by Green and Desarbo; we discussed an advertising strategy application.

On Alternative Methods For Conjoint Analysis

Leigh, Mackay, and Summers have presented an interesting study on alternative methods for conjoint analysis. The objective of their study was to evaluate full and fractional experimental and various methods of data collection: rank order, pair-comparisons, graded pair-comparisons, subjective estimates, and rating scales. The evaluative criteria were reliability and validity. The study concluded that the less fractionated designs were more reliable than the more fractionated designs; and that data collection methods involving comparative judgments (i.e., pair-comparisons, graded pair-comparisons, and ranking) were more reliable than profile stimulus sets. Based upon small sample sizes, however, the authors assert that the results must be tentively held. Hence, they agree that the findings are suggestive. The implication, of course, is that if the cell sample sizes had been larger, the results would be more meaningful estimates of reliability and validity. We show below, however, that this conclusion may be false.

Leigh, et al. use the test-retest correlation as a measure of temporal stability. They state that "Test-retest methods are a common way of measuring the temporal stability of Consumer's Responses (p. 318)." Their distinctions between temporal stability and structural reliability follow the work of McCullough and Best (1979). McCullough and Best (1979) have stated that "The stability of a measurement is related to the reproduction of measurement results at different points in time. This aspect of reliability generally has been inferred by the correlation between test-retest measurements over some specified time interval (p. 26-27)." Additionally, McCullough and Best (1976) have stated that structural reliability relates to systematic error. Let us first state that these definitions are not standard psychometric terms. Ordinarily when systematic changes are accounted for, the degree to which an instrument replicates its measurements is called the reliability of measurement. On the other hand, given measurement that contains no random error, the degree to which an instrument replicates its measurements is called the stability of measurement (Heise 1979, Wiley and Wiley 1971). Nonetheless, Leigh, et al. define temporal stability as reliability and structural reliability as stability; hence, one is not sure what they are really after. More importantly, Leigh, et al. used the test-retest correlation coefficient; it is shown below that one test-retest correlation does allow one to separate reliability from stability.

Separating Reliability From Stability

To demonstrate why a single test-retest correlation does not provide a good estimate of reliability or stability, we lean heavily upon the work of Heise (1971). His work stems from Coleman (1968), classical psychometrics (Lord and Novick 1968) and from path analysis. Let us begin with path diagram of standardized test-retest measurements given in Figure 5.

FIGURE 5

In this diagram, the coefficient $\beta_{\tau_1 \tau_2}$ is the standardized path coefficient representing the degree to which the true score at time 1, τ_1 , "causes" the true score, τ_2 , at time 2. In this context, $\beta_{\tau_1 \tau_2}$ is identical to the correlation between true scores, i.e., $r_{\tau_1 \tau_2}$. The coefficient $\beta_{\tau_1 \tau_2}$ (or $r_{\tau_1 \tau_2}$) is an estimate of stability, i.e., the degree to which test-retest measurements covary when measurement error is removed. The coefficients $\lambda_{\tau_1 x_1}$ and $\lambda_{\tau_2 x_2}$ are path coefficients reflecting the degree to which the true scores "cause" the observed measurements, x_1 and x_2 . These coefficients are identical to the correlation of the observed measurements with the true scores, i.e., $r_{x_1 \tau_1}$ and $r_{x_2 \tau_2}$. The square of $\lambda_{\tau_1 x_1}$ (or $r_{x_1 \tau_1}^2$) is defined as the reliability of measurement for x_1 (Lord and Novick 1968). The coefficients $\lambda_{e_1 x_1}$ and $\lambda_{e_2 x_2}$ are coefficients reflecting the degree to which random measurement errors "cause" the observed measurements. Since, we assume standardized variables, the variance of x_1 and x_2 is equal to one; hence,

$$\lambda_{e_1 x_1} = \sqrt{1 - \lambda_{\tau_1 x_1}^2}, \tag{1}$$

$$\lambda_{e_2 x_2} = \sqrt{1 - \lambda_{\tau_2 x_2}^2}.$$

The coefficient $\beta_{u_2 \tau_2}$ represents systematic changes produced in τ_2 ; it is given as:

$$\beta_{u_2 \tau_2} = \sqrt{1 - \beta_{\tau_1 \tau_2}^2}. \tag{2}$$

For the above path model we assume that measurement errors are mutually uncorrelated, and that measurement errors correlate only with the respective observed measurements. Following the rules of path analysis the test-retest correlation, $r_{x_1 x_2}$, is defined as:

$$r_{x_1 x_2} = \lambda_{\tau_1 x_1} \beta_{\tau_1 \tau_2} \lambda_{\tau_2 x_2}. \tag{3}$$

Hence, with three unknowns in one equation, we can easily see that test-retest correlation does not enable one to separate reliability ($\lambda_{\tau_1 x_1}^2$ or $\lambda_{\tau_2 x_2}^2$) from stability,

$\beta_{\tau_1 \tau_2}$. Even if we assume that the reliability of the instrument is constant over the two time periods,

$$\lambda_{\tau_1 x_1}^2 = \lambda_{\tau_2 x_2}^2 = \lambda_{\tau x}^2, \tag{4}$$

we still have an unsatisfactory situation:

$$r_{x_1 x_2} = \lambda_{\tau x}^2 \beta_{\tau_1 \tau_2}. \tag{5}$$

Following Coleman's (1968) lead, Heise (1971) demonstrated that it takes at least three time periods to separate reliability from stability. Below we provide a path diagram for the test-retest paradigm--assuming that the reliability of the instrument is constant (see Figure 6).

FIGURE 6

If the assumptions stated above are preserved, and if it is assumed that the disturbances, u_2 and u_3 , are uncorrelated, we may use the rules of path analysis to write:

$$r_{x_1 x_2} = \lambda_{\tau x}^2 \beta_{\tau_1 \tau_2}$$

$$r_{x_2 x_3} = \lambda_{\tau x}^2 \beta_{\tau_2 \tau_3} \tag{6}$$

$$r_{x_1 x_3} = \lambda_{\tau x}^2 \beta_{\tau_1 \tau_2} \beta_{\tau_2 \tau_3}.$$

The first two equations may be written as:

$$\beta_{\tau_1\tau_2} = \frac{r_{x_1x_2}}{\lambda_{\tau_x}^2} \quad (7)$$

$$\beta_{\tau_2\tau_3} = \frac{r_{x_2x_3}}{\lambda_{\tau_x}^2}$$

Making the appropriate substitutions into the bottom of equation 6 and solving for $\lambda_{\tau_x}^2$ yields:

$$\lambda_{\tau_x}^2 = \frac{r_{x_1x_2} r_{x_2x_3}}{r_{x_1x_3}} \quad (8)$$

Once the reliability of measurement, $\lambda_{\tau_x}^2$, is found, the observed correlations may be corrected for attenuation. These corrected correlations, $\beta_{\tau_1\tau_2}$, $\beta_{\tau_2\tau_3}$, and $\beta_{\tau_1\tau_3}$, are the desired stability coefficients.

If the assumption that the reliability of three measurements is constant over time seems unrealistic, Wiley and Wiley (1971) present a path analytic model in which this assumption is relaxed.

Leigh, *et al.* used the test-retest correlation as a measure of "temporal stability." Our discussion, however, demonstrated that the test-retest correlation confounds stability with reliability. Furthermore, one test-retest correlation does not permit one to separate stability from reliability. We show that it takes at least three measurements (i.e., test-test-retest) for the estimation of stability.

Additional Comments

One interesting result obtained by Leigh, Mackay and Summers is that the average test-retest correlation of the direct dollar metric estimates of the part worths is greater than the average test-retest correlation of the part worths derived by conjoint analysis: .500 (Table 2) vs .385 (Table 1). The difference may not be significant because of the relatively small sample size.¹ In any event, one may wonder whether the direct part worth estimates have more predictive validity than those derived by conjoint analysis. Leigh *et al.* could have used the part worth estimates obtained (directly and by conjoint analysis) the first time to predict the rankings or ratings of the stimuli evaluated the second time. To be able to predict with the direct part worth estimates it is necessary to also know which level is preferred for each attribute and respondent. This can be obtained with one direct question for each attribute. Leigh *et al.* (apparently) did not have this information and thus could not estimate the predictive validity of the direct part worth estimates.

In a study that involved 41 respondents Cattin and Weinberger (1980, Tables 3 and 7, p. 782-783) found the predictive validity of direct part worth estimates to be very close to the predictive validity of part worths

¹In this case, the t-value would have to be taken with a grain of salt. As indicated by the authors themselves in their reply to a referee, a t-test is "strictly speaking not appropriate." This is because different data collection methods were used to obtain the part worth estimates derived by conjoint analysis. Hence, the variances of the test-retest correlations may vary across methods.

derived by conjoint analysis. Of course, direct part worth estimates can have biases. To reduce the biases it is necessary to tell the respondents which levels they should refer to and to think that the products are always exactly the same (on all attributes) except on the attribute they are evaluating. Even so, it has been found in several studies that respondents tend to underestimate the importance of important attributes and to overestimate the importance of lesser important attributes: see, for instance, Scott and Wright (1976, p. 214) and Cattin and Weinberger (1980, Table 6). However, Green (1979) has shown by simulation that the market share predictions obtained with such distorted part worth values are quite close to the market share predictions obtained with "true" non-distorted part worth values. Hence, the effect of this bias on market simulation results is relatively small. Actually, direct part worth estimates are used commercially: e.g., Aaker and Day (1980, p. 206).

If direct part worth estimates have relatively good predictive validity, combining them (somehow) with conjoint data might improve predictive validity. Bayesian regression procedures derived from Stein (1960) can be used to combine the two sets of data. Cattin and Danes (1981) have shown analytically and empirically that some improvement in predictive validity can thus be achieved.

Limits To Accuracy In Conjoint Analysis

Acito and Olshavsky's hypothesis is that the predictive validity obtained with conjoint data (using the full profile approach) in which each attribute is defined with two levels is superior to the predictive validity obtained if each attribute is defined with three levels. Acito and Olshavsky tested this hypothesis in the case where the number of stimuli evaluated by respondents is the same in both the two and three levels cases and where part worth attribute utilities (rather than utility functions) are estimated (i.e., one more parameter is estimated for each attribute in the three levels case compared to the two levels case).

The arguments in favor of the hypothesis, as stated by Acito and Olshavsky, are the following. First, the parameter estimates obtained in the three levels case are less reliable because there are less degrees of freedom (due to the fact that there is one more parameter estimated for each attribute). Second, the respondents are given more information in the three levels case (i.e., stimuli are defined on three levels instead of two) which produces more confusion, carelessness, and thus more noise in the data. It should be pointed out that the hypothesis applies primarily to the full profile approach (whereby the stimuli evaluated by the respondents are defined on all attributes). If one compares, for instance, the predictive validity obtained with ten (3 x 3) tradeoff matrices to the predictive validity obtained with ten (2 x 2) tradeoff matrices, the hypothesis is likely not to hold.

Acito and Olshavsky tested their hypothesis using twenty MBA students, ten of which were assigned to each of three levels and two levels designs. In both cases, the attribute utilities were estimated using MONANOVA on the rankings of 23 stimuli.² The predictions obtained on validation

²The 23 stimuli were taken from orthogonal design plans of 25 assemblies for the three level case and 24 for the two level case. However, the authors deleted two assemblies from the three level design and one assembly from the two-level design. Hence, the designs were not orthogonal.

data show that Acito and Olshavsky's hypothesis seems to be correct. Some of the results are significant even though the sample size was small.

One may wonder whether the superior predictive validity obtained with the two-levels design is due (a) to more degrees of freedom, or (b) to less noise in the data, or (c) to both. If (a) is the reason, one could improve the predictive validity in the three-levels case by increasing the number of stimuli (thus decreasing the number of degrees of freedom). If the amount of noise is the same, the predictive validities obtained with both designs would be the same if the "true" attribute utilities could be obtained. However, the estimated part worths have errors because they are based on a limited number of observations, and the error is expected to be greater with the three-levels design because there are less degrees of freedom. In other words, the resulting shrinkage in the correlation reflected in the predictive validity is expected to be greater in the three-levels case. Some insight in the difference in expected shrinkage (obtained with the two vs three levels designs) can be gained using equation 8 or 9 in (Cattin 1980, p. 410).

There is one way to find out whether there is more noise in the data in the three-levels case compared to the two-levels case.³ It involves assuming linear utility functions for each attribute in the three-levels case, thus estimating one parameter for each attribute (i.e., the same as in the two-levels case). In these conditions, the differences in predictive validity is due to the amount of noise and not to differences in the number of degrees of freedom. However, if linear utility functions are fitted in the three-levels case, the violations of the a priori attribute utilities would still be the same: i.e., higher in the three-levels case than in the two-levels case (Acito and Olshavsky 1980, Table 2). Hence, it appears that there might indeed be more noise in the three-levels case than in the two-levels case, and that the two-levels design would still produce higher predictive validities even if the number of stimuli (to be evaluated by respondents) is increased in the three-levels design.

Whether and by how much two-levels designs are found to have more predictive validity than three-levels designs depend upon several factors including the type of respondents and the type of attributes. If the respondents are more involved, there should be less noise and this could improve the results of a three-levels design compared to a two-levels design. However, whenever two-levels designs do produce data with less noise and increase (substantially enough) the predictive validity (when the full profile approach is used), it then becomes appropriate not to have more than two levels whenever possible. One way to proceed is to ask the respondents to position the levels of each attribute on (say) an 11-point scale where the least preferred and most preferred levels occupy the two ends (which can be asked of the respondents), and to then have the same respondents evaluate stimuli that are defined using only two levels for each attribute. See, for instance, Wind, Grashof and Goldhar (1978, p. 29-30). This procedure can be used with both discrete and continuous attributes. However, there

³In the three-levels case, Acito and Olshavsky used linear interpolation between part worths to estimate the utility of intermediate levels. Pekelman and Sen (1979) have shown that fitting a (quadratic) curve through the part worths improves predictive validity and is thus more appropriate than interpolation. However, this would have changed the results obtained by Acito and Olshavsky only in the case of the prediction of actual brands (and not in the case of the prediction of "holdout" ranks). It thus appears that the results obtained with the two-levels design would still have been superior to the results obtained with the three-levels designs.

might be some problems with continuous attributes especially if the attribute utility is expected to go through a minimum or a maximum (e.g., sugar content). In this case, it might still be best to have more than two levels in the conjoint design.

A final point regarding Acito and Olshavsky's study concerns the use of MONANOVA as the procedure for estimating part worths. MONANOVA is an iterative procedure that tries to minimize stress. However, it can end up in a local rather than global optimum. In a Monte Carlo simulation study, Cattin and Wittink (1976, Table 4, p. 20) found that an estimation procedure based on the maximum likelihood of the LOGIT model led to part worth estimates with lower stress values than MONANOVA more often than not. Hence, the simulation results obtained by Acito and Olshavsky to determine the stress values produced with random data are not very meaningful because there is no guarantee that MONANOVA reached the global optimum. With nonmetric data it is more appropriate to use LINMAP or a LOGIT approach, while regression can be used with metric data. For the tradeoffs between these methods, see, for instance, Green and Srinivasan (1978, p. 112-114).

INITIAL MARKET RESEARCH STEPS TOWARD
A MODEL OF THE MILITARY ENLISTMENT DECISION

Shel Feldman, Associates for Research in Behavior, Inc.
A. J. Martin, Office of the Secretary of Defense

Abstract

A large-scale tracking study of the propensity of young men and women to enlist in the National Guard or Reserves provided an opportunity to develop and test a regression-based model of a critical life decision. An Ordinary Least Squares (OLS) model comprising nine independent variables replicated in double cross-validations across randomly split subsamples in each of three independent samples of 1500 persons, in the baseline year. In each sample (non-veteran men, non-veteran women, veteran men), moreover, the model accounted for half the variance of the criterion, based on eight measures of military enlistment propensity. Follow-up interviews of 711 non-veteran respondents, a year later, demonstrated the predictive validity of the measure.

Problem

It often seems difficult to model important life decisions along the lines of problem-solving and consumer purchasing. Although choice of a career and choice of a mate are usually acknowledged to contain elements of rationality, for example, stress is often laid to chance factors and the unique occurrences that differentiate between outcomes. In part, this difficulty may reflect our need to assert uniqueness and free will in those areas most central to our self-concept. In part, it may also arise from a focus on the particular job or spouse chosen -- rather than on the class of jobs or of spouses -- and the consequent inability to obtain and analyze data on a large set of similar decisions. A large-scale study on the military enlistment propensity of young men and women offered the opportunity to develop and test a rational model of that important life decision.

Background

Successful manning of the All-Volunteer Force requires encouraging more than 650,000 young people to choose military service each year. The voluntary nature of the transaction with potential enlistees has focussed the Department of Defense on the need to consider the nature of its product -- military service --, its positioning, and its promotion efforts through advertising and recruiting, as well as on its pricing variable (enlistment standards). In Fiscal Year 1981, the budget for recruiting will reach \$970 million. Much market research will be aimed at understanding the perceptions of potential enlistees, and their decision process regarding military service, in order to carry out recruiting most effectively.

The data reported here are derived from a tracking study of awareness and attitudes toward enlistment into the Reserve Components (Associates for Research in Behavior, 1979). The National Guard and Reserves are part-time military units requiring a specified number of training periods each year, following initial basic training and specialty schools, and provide back-up capability for the Active (full-time) Forces. These components will require nearly 250,000 enlistments in Fiscal Year 1981, from among young men and women with no prior military service (NPS) and those who are veterans of the Active Forces.

The baseline data for this tracking study were collected in Fall, 1978, from a total of 4503 persons. One sample, of 1500, was composed of NPS males, between the ages of 17 1/2 and 26, who had completed no more than two years of college education. A second sample, of 1502, was composed of comparable NPS females. The third sample was composed of 1501 male veterans, separated from active service within the previous five years.

The data were collected by phone, in interviews of approximately 30 minutes duration, by trained professional interviewers. The NPS samples were obtained by random digit dialing within specified area codes and exchanges, chosen to form an interpenetrating block design weighted by accessibility to U.S. Army Reserve centers. The veterans were a stratified random sample of all men separated from the Active Forces in the designated time period and eligible for re-enlistment. Each sample was randomly divided into two equal subsamples to test the reliability of various results, including factor analyses and regressions.

Propensity to enlist in the Reserve Components will be reported in two ways. Each is a verbal measure of intention. The "standard" propensity measure indicates the respondent's highest expressed likelihood of serving in any of the six components (Army National Guard, Air Force Reserve, etc.), as indicated on a four-point scale. Thus, if a respondent says she will "definitely" serve in the Navy Reserve, but "probably not" in any of the others, she will be scored "definitely." And if a respondent says he will "probably" serve when asked about each of the components, he will be scored "probably." Responses to questions on each component are highly correlated, particularly for the NPS respondents, who tend not to differentiate between components. In the 1978 data, positive propensity ("definitely" or "probably" enlist responses to at least one component) was shown by 24.7 percent of NPS males, 12.9 percent of NPS females, and 21.0 percent of male veterans.

The "general" propensity measure was developed for use in the regression model, in order to remedy certain deficiencies of the "standard" measure. The "general" measure is a summative index of eight items reflecting military enlistment propensity under a number of conditions. These include the "standard" measure as well as responses to questions on propensity to enlist in the Active Forces, propensity to enlist in the Reserves under different lengths of enlistment contract, and propensity to enlist in the Active Forces or in the Reserves, were there a national service requirement. This summative index has an internal consistency index in the high .80's in each sample, much greater sensitivity than the standard measure, and a far less skewed response surface.

The independent variables on which "general" propensity was regressed were chosen to test a simple decision-making model of the enlistment process. The attempt was made to demonstrate that a single parsimonious model could account for a major share of the variance in each sample. Current work is directed at improving measures and the structural description of the model, given this initial demonstration.

The model posits that enlistment propensity is based on background attitudes, a benefit-cost valuation regarding the prospects of service, and factors peculiar to the

particular life situation of the respondent. Background attitudes include general acceptance or rejection of the military in American life, willingness or unwillingness to accept impositions on individual freedom in order to accomplish social goals (in the form of a national service requirement), and degree of need to be with others. Perceived benefits of service in a Reserve Component were measured with respect to opportunities to achieve life goals and opportunities to participate in a team. Perceived costs of service were measured with respect to loss of opportunities to be with family or friends, or to achieve further educational or occupational progress in the time allotted to service, and with respect to other negative outcomes, such as potential harassment by superiors. The respondent's current life situation was measured with respect to job commitment and perceived support for enlistment among current peers.

TABLE 1

"General" Propensity Regressed on Selected Variables

Variable	Male Veterans (N = 1248) ^{a/}	
	Est. Weight	St. Error
General predisposing attitudes		
Acceptance of the military ^{b/}	.976	.114
Acceptance of the imposition of a National Service Requirement ^{c/}	.333	.075
High need to be with other people ^{b/}	.997	.115
Anticipated gains from service		
Achievement of important individual life goals ^{b/}	.354	.031
Benefits of being a member of a team ^{b/}	1.380	.124
Anticipated costs of service		
Perceived opportunity costs ^{b/}	-.281	.122
The occurrence of negatively-valued situations ^{b/}	-.368	.114
Impacts of current life situations		
Commitment to present job situation ^{d/}	-.230	.066
Perceived social approval for enlistment ^{e/}	.870	.122
Constant term ^{f/}	20.429	
Multiple correlation	.678	
Coefficient of determination (R ²)	.460	

a/ Cases with missing data omitted.

b/ Factor scores; Mean = 0.

c/ 1 = strongly opposed; 5 = strongly in favor.

d/ Expects to look for job, or to change jobs: 1 = very likely; 5 = very unlikely.

e/ Others would be: 1 = very displeased; 5 = very pleased.

f/ 8 = least propensity to enlist; 34 = highest propensity.

Results

Perceived benefits and costs of service were measured with factorially-derived scales, as were background attitudes toward the military and regarding the need to be with others. The scales were derived from independent principal axis factoring in each subsample of each of the three samples. Comparability was tested using Schonemann's approach (1966; Schonemann & Carroll, 1970). Surviving factors were rotated to maximize interpretability. Resultant scales were constructed, and those with moderate to high internal consistency scores were retained for use in regression analyses of "general" propensity.

The results of the OLS regression analysis in the sample of male veterans are shown in Table 1. These results are clearly consonant with the model proposed. Each of the variables considered contributes significantly to the explanation of "general" propensity, and virtually half of the variance is explained, even without any correction for attenuation. (It should be noted, however, that none of the variables offers great leverage for altering "general" propensity, when evaluated at the point of means.)

The regression results for the male veterans sample were initially developed in each of the two random subsamples involved, and double cross-validated. Moreover, the same model applies to each of the NPS samples, with double cross-validation, accounting for 48.8 percent of the variance in "general" propensity among NPS males, and 47.5 percent among NPS females. With one exception, the variables involved are all significant in each of the other samples as well. (The relative importance of some are sample-dependent, however. For example, the estimated weight of "acceptance of the military" among NPS females is less than half as large as it is among NPS males or veteran males.)

The one exception to the general significance of estimated weights across samples occurs with respect to opportunity costs. The greater the perception of service in the Reserves as taking time from family, friends, job, or school, the lower the enlistment propensity of male veterans. However, this perception is not significantly related to "general" propensity among NPS males, and it is positively related to "general" propensity among NPS females. Presumably, these differences reflect differences in the life cycle position and the commitments of the members of the different samples, and should be explicitly incorporated in the interaction terms of more complete future structural models.

The regression equations were applied to the data from new independent samples in the Fall, 1979 wave of the tracking study. They accounted for between 20 and 30 percent of the variance in the several samples, despite changes in the wording of certain specific items in the predictors, changes in the composition of the "general" propensity measure, and changes in the social and political context (including the onset of the Iranian crisis).

Results of a Follow-up Study

The major implication of the regression analyses for this paper is that a single parsimonious OLS regression model can capture half the variance in a verbal measure of intention -- intention to undertake or not to undertake an important life change.

But is there any predictive validity to the verbal measure of intention? A follow-up study provided an opportunity to test this.

A year after the original interview, attempts were made to call every NPS respondent in the original sample who had indicated a definite or probable intention to join any of the Reserve Components in Fall, 1978. Attempts were also made to call a random sample of other NPS respondents, of equal size. In total, new interviews were obtained with 372 respondents who had expressed positive enlistment propensity (67 percent of the target group), and with 339 others (60 percent of that target group). These interviews, of about 15 minutes duration, obtained data for estimating the stability of various measures, but concentrated on obtaining reports of important behavior in the past year. The focus of behavioral reports included marriage, job changes, going to school, and military-related incidents, such as responding to military advertising, seeing a recruiter and actually applying to join the military.

Two analyses are of immediate interest. The proportion of respondents with positive enlistment propensity on the "standard" measure who engaged in each of several enlistment-related behaviors is shown in the left-hand column of Table 2. The proportion of others who engaged in each of those behaviors is shown in the center column. It is evident that the several behaviors form a continuum. (Guttman scalability is .85.) More important for present purposes, positive propensity respondents are clearly more likely to engage in each. In fact, the ratio of the proportion of positive propensity respondents to others increases at each step.

TABLE 2
Predictive Validity of Propensity Measures

Enlistment-Related Behavior	Proportion Reporting Designated Behavior, By "Standard" Propensity		r, 1978 "General" Propensity ^{a/}
	Positive (N = 372)	Negative (N = 339)	
Sent for literature or went to see recruiter	.323	.103	.29*
Attended an open house	.113	.032	.16*
Applied to a military service	.078	.012	.19*
Accepted for military service	.048	.006	.14*
Joined a military unit	.035	--	.10*

* $p < .05$

a/ Cases with missing data excluded.

The correlation of 1978 "general" propensity with 1979 reports of engaging in each of the relevant behaviors, over all respondents, is shown in the right-most column of Table 2. Each is statistically significant. The lowest coefficients are found in relation to behaviors that are (compared to applying) largely under the control of others (being accepted for service and then actually joining).

Discussion

Whatever its defects, the verbal measure of propensity to enlist in the military does predict whether or not a respondent is likely to take some steps toward enlistment. Not surprisingly, predictive validity is greater for more proximate behaviors, and for those more under the control of the respondent. This should be kept in mind in further measurement work and further modeling. It may also suggest some shifting of recruiting and advertising strategy away from stress on the final goal of enlistment. Given that a sequence of behaviors is clearly involved, it may be useful to shift more resources to encouraging more immediate behaviors, such as seeing a recruiter.

It cannot be said, at this time, that propensity is the outcome of the variables included in the OLS regression model. The last two decades of attitudinal research show that attitudinal changes, behavioral changes, and changes in the social context are related in a far more complex fashion than was formerly accepted. Ongoing work is focusing on more complex modeling of the enlistment process, including recognition of simultaneity effects. Nonetheless, it is clearly possible to develop a summary

index of enlistment propensity from measures of other attitudes, and to predict the likelihood of enlistment-related behavior from scores on that index. Further development of a rational model of this important life decision seems appropriate and useful.

MARKETING ACTION BASED ON CONSUMER DECISION PROCESSES:
THE CASE FOR MICRO-BEHAVIORAL SIMULATION

Richard A. Westwood, The Beaumont Organization, Ltd.
Harry S. Sunenshine, Heublein Inc.

Abstract

This case history describes how a number of sophisticated methodologies were brought to bear upon the strategic issues facing an established brand, and how results were eventually implemented by management. The research design was based on the SCIMITAR Research system. Techniques discussed include Conjoint Measurement, Correspondence Analysis, Brand Progress Analysis, Brand Impact Analysis, Hierarchical Cluster Analysis, and Micro-behavioral Simulation.

Introduction

Designing medium-term marketing strategy poses difficult challenges for researcher and manager alike. By its very nature, strategic design demands that several facets of the current and future market be synthesized within an action plan — including for example, immediate and more distant competitive frames; potential cannibalization between company brands; and the vulnerability of strategies to competitive response.

In attempting to deal with such broad ranges of issues, traditional research methods have generally adopted abstract views of the market. Psychographic segmentation provides a current, and popular, example of this type of abstraction. But, although abstract research results are often fascinating and insightful, their translation into action decisions tends to be vague and ambiguous. On the other hand, more specific and directly actionable methods run the risk of lacking generalizability, even of being trivial to the issues facing the strategic designer.

A number of technically advanced research methods, in particular micro-behavioral simulation, offer more powerful ways to approach strategic issues. The primary appeal of simulation lies in its ability to be sufficiently specific to relate directly to decision making yet, at the same time, sufficiently flexible to encompass a wide range of issues and contingencies.

This case history discusses how several sophisticated techniques, including simulation, were used to design strategy for a Heublein brand. The particular methodology described is Beaumont's SCIMITAR system, which comprises a suite of data gathering, analytic, and simulation approaches. Central to this system is the use of a model of the consumer brand choice process to integrate perceptual data with Conjoint Measurement, leading to several powerful analysis and simulation possibilities.

At the time of publication, early phases of the strategy have already been successfully implemented. Other aspects of the plan will be deployed in the future and, accordingly, the overall strategy remains confidential. In order to safeguard Heublein's security interests, while presenting data that have integrity for the research audience, this paper adopts the expedient of changing labels. The market under discussion, its attributes, and the key demographic groups, have been disguised. In the main, the actual results reported have not been changed, except in those few cases where they would permit the alert reader to infer which of Heublein's markets is the subject of this discussion.

Background

For a number of years, Heublein's brand had dominated the packaged goods category that was its primary source of business. Although two major national competitors existed, much of the remaining competition was limited to several small regional brands that were unable to dislodge the Heublein brand from its brand leader position in their markets.

More recently, the brand had begun to mature. Concurrently, its product category was becoming increasingly competitive. Where there had been one or two major brands, there were now four or five, some of whom posed serious competitive challenges.

Complicating matters, the competitive frame was by no means clearcut. Although Heublein's brand belonged to a product category that was clearly definable in manufacturer terms, it also appeared to compete with members of certain other categories. The fact that some of these adjacent product categories were growing more rapidly than Heublein's brand, or its immediate category as a whole, suggested that they might be limiting its opportunities.

Given the pressures upon its brand, management faced a two-fold challenge: to mount an effective defense against the recent, and vigorous, immediate competitors; and to create new growth at the expense of adjacent product categories. There was a need for research that would identify how Heublein might achieve these goals.

Behavioral Focus

It was clear that descriptive research methods would not be sufficient to address these objectives. Instead, it would be necessary to explain the process whereby consumers made their brand choice decisions, and to predict how these decisions might be changed by a variety of marketing actions.

The SCIMITAR research system was adopted for this research because it provided such a focus on the consumer decision process. The methodologies within the system were used to construct a three-component research program.

Research Program

The three components within the overall research program were as follows:

Preliminary Qualitative Research was conducted to provide the basis for questionnaire design.

An Immediate Category Study was the largest scale component within the research program, reflecting management's prioritization of the need to regain ground that had been lost to recent competitors, and to strengthen its brand against further attack.

A Total Market Perceptual Study was conducted in order to reveal the broader competitive perspective, and to be able to assess the more general implications of strategic actions.

Preliminary Qualitative Research

The preliminary phase of a strategic research program is the foundation upon which all subsequent results are built, and as such is crucial to project success.

As a first step, all pertinent past research was reviewed. This review was then augmented by qualitative Protocol Interviews with 16 individuals, including a variety of demographic and behavioral consumer types.

Protocol Interviews are a depth research methodology, designed to probe the brand choice process by having individual respondents perform a series of "choice tasks". For example, one task requires respondents to make a brand choice from seven blank packs, using the interviewer as a totally reliable information source. The interviewer uses each session to elicit the information used in brand choice decisions, the form in which information is cognitively structured, and the manner in which it is processed. The parameters appearing in individuals' choices are then generalized, and re-expressed in questionnaire form.

The semantic and conceptual structures within a strategic questionnaire act as a common language between the manufacturer and the market. To be effective, they must be capable of translating manufacturer concerns into consumer terms, and vice versa. Accordingly, consumer variables derived from the exploratory research were tested against management's own decision criteria. This resulted in some minor modifications to the questionnaires, including the addition of two attributes to the list of market descriptors.

Immediate Category Study

In this, the central component of the research program, 1,000 category users were interviewed in their own homes, using a 90 minute questionnaire. Based on the fact that differences between men and women were known to be important in the market, the sample was structured into two representative samples of 500 men and 500 women respectively.

The questionnaire was based on SCIMITAR methodology, which has been discussed in detail elsewhere (see Beazley and Westwood, 1976, Palmer and Westwood, 1976) and is therefore reviewed here only briefly.

In essence, the methodology reconstructs respondents' choice behavior, based on measurements of their requirements from the product field, and their perceptions of brands.

Conjoint Measurement is employed to measure requirements from the product field, using the approach discussed in Westwood (1973). The respondent states "trade-offs" between pairs of attributes, providing data that indicates the utility he derives from each attribute, and how he processes the attribute when making choices. The respondent also rates several brands across the same list of attributes. Conjoint and brand rating data are integrated at the individual respondent level, thereby explaining current choices, and simulating new choices under changing conditions.

22 attributes, derived from the Preliminary Qualitative Research, were investigated in the questionnaire. Additionally, extensive data were gathered regarding each respondent's purchase and usage behavior, demographics, and psychographics.

Role of the Heavy User

Analysis of usage patterns revealed heavy users to be extremely important to the product category, 75% of all consumption being accounted for by only 28% of consumers.

Furthermore, these heavy users tended to be demographically distinct and hence directly approachable through marketing action. For example, they were much more prevalent among men than among women. Based on this finding, much of the subsequent analysis focussed on the heavy user: in particular, how to attract him to Heublein's brand.

Brand Progress Analysis

The extent of the threat posed by recently launched national competitors was gauged using Brand Progress Analysis. This simple, but effective, analysis of brand strength pictures sales results in terms of a flow of consumers between various experiential states — from lack of awareness to awareness; from trial to acceptance; etc. In the current application, it was used to diagnose the limits to each major competitor's growth.

Among heavy category users, Heublein's brand compared to one of its newer national competitors as follows:

TABLE 1
BRAND PROGRESS ANALYSIS AMONG HEAVY USERS

	Unaware to Aware	Aware to Knowledge	Knowledge to Trial	Trial to Usage	Usage to Regular
Heublein brand	100%	100%	100%	84%	51%
Major competitor	88%	95%	95%	83%	61%

While Heublein's brand still benefitted from higher awareness levels, the competitor appeared to be able to match its trial and acceptance levels once awareness had been developed, and was superior in converting occasional users to regular users.

It appeared that this competitor had the potential eventually to gain brand leadership among heavy users, provided that it could increase its awareness level while simply maintaining its performance in other respects. Comparison of share patterns among consumers aware and unaware of the brand tended to confirm this finding:

TABLE 2
BRAND SHARES AMONG CONSUMERS AWARE AND UNAWARE OF COMPETITOR

	Unaware of competitor		Aware of competitor	
	Light Users	Heavy Users	Light Users	Heavy Users
Heublein brand	73%	81%	53%	36%
Major competitor	-	-	23%	47%
Other brands	27%	19%	24%	17%

Brand Progress Analysis had revealed a major competitive threat, especially among the heavy users who had been shown to be of major importance to the category. Heavy users who became aware of the new competitor accorded it the majority of their usage. Unless countered, this brand could be expected to make significant inroads into the core of category volume, largely at Heublein's expense.

Management's prioritization of defensive strategy was thus strongly endorsed by research findings, and attention was now focussed on how such a strategy might be developed.

Consumer Wants

The logical starting point for strategic development is the examination of the factors that determine consumers' brand choices. In this study, the importances of choice criteria were measured in terms of utility scores derived from Conjoint Measurement. Figure 1 displays the overall utilities attached to various attributes by the average consumer:

FIGURE 1
IMPORTANCES OF ATTRIBUTES TO THE AVERAGE CONSUMER

Similar analyses were conducted within demographic and behavioral groups, and significant differences were found. For example, heavy users were shown to attach considerably more importance to children's enjoyment of the product — a factor that Heublein had not promoted actively, but that was a central aspect of a growing competitor's positioning. Attributes such as naturalness and wholesomeness, that had been the basis of recent Heublein advertising campaigns, were less important to heavy users.

Satisfaction with Brands

While the analysis of consumer wants showed what was important to consumers, and provided first suggestions regarding how the market segmented, it did not reveal where leverage might exist against current competition. Accordingly,

Brand Impact Analysis was used to combine utility and branding data, and thereby to reveal the extent of "unfulfilled utility" remaining within each attribute.

Figure 2 provides an example of Brand Impact Analysis, referring specifically to Heavy Users' images of the brands they consume regularly. The overall length of each bar represents the total utility associated with a particular attribute; the shaded portion shows the extent to which brands currently satisfy consumers' wants; and the remaining unshaded area reveals the extent of unfulfilled utility within the attribute. Thus, an attribute displaying a sizeable unshaded area would comprise a vulnerability of current brands that might profitably be attacked.

FIGURE 2
BRAND IMPACT ANALYSIS: HEAVY CATEGORY USERS

Brand Impact Analysis revealed a high degree of product satisfaction among heavy users. It suggested that major share gains could not be expected to result from improvements on isolated individual attributes, since these would not provide a compelling point of superiority. Significant leverage might only be possible if images were shifted on several attributes in concert.

Other Brand Impact Analyses, among various brand user groups, showed that the users of major competitors perceived a number of disadvantages in Heublein's brand. These could, in the main, be attributed to known aspects of product formulation, and their rectification was made an immediate marketing priority.

Total Market Perceptual Study

The Total Market Perceptual study was conducted to investigate the nature and extent of inter-category competition. In-home interviews were conducted among a representative sample of 350 respondents. The questionnaire required respondents to assemble 32 brands into groups of potentially substitutable items; to indicate which brand groups were suitable for use in each of a list of 21 situations; and to indicate which attributes were associated with each brand group. Volume usage data were also gathered for each situation.

The resultant data were subjected to a variety of multivariate and multidimensional scaling analyses, of which two are discussed below.

Market Structure

Johnson's Hierarchical Cluster Analysis was applied to the brand grouping data to determine the consumer's categorization of the market, providing a "family tree" of brand relationships as illustrated in Figure 3.

FIGURE 3
HIERARCHICAL CLUSTER ANALYSIS OF BRAND RELATIONSHIPS

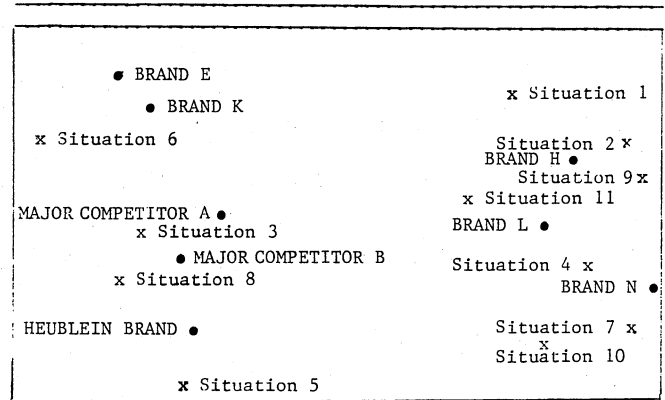

In general, the results suggested that consumers classified brands in much the same way as manufacturers. Thus, the primary competition to Heublein's brand was the immediate product category as the company had traditionally defined it. However, there were also some surprises elsewhere in the market structure. For example, two product categories that shared certain key ingredients, but that had previously been regarded as distinct, were shown to be highly substitutable, and virtually a single product category from the consumer standpoint.

Usage Patterns

The fact that brands and products belong to different perceived categories should not be taken to imply that they are non-competitive. Danish pastry and sausages belong to different categories, but compete for usage at breakfast. Taxis and bicycles are different products, but the consumer may choose between them during a transit strike. In general, categories that consumers regard as distinct may nonetheless compete within particular usage situations.

In the current study, patterns of cross-category competition were revealed by applying Correspondence Analysis to the 'brands by situations' data referred to above. This analytic method, analogous to both multidimensional scaling and principal components analysis, plotted brands and situations into a single space, as illustrated in Figure 4.

FIGURE 4
CORRESPONDENCE ANALYSIS OF USAGE COMPETITION

Like its major competitors A and B, Heublein's brand was found to be positioned towards a few high-volume situations (3, 8, and 5). However, within this positioning, its usage skewed towards the 'special purpose' Situation 5 rather than to the more mainstream Situations 3 and 8. Short term volume gains appeared to be possible if the brand could become more competitive in mainstream contexts.

Taking a longer term perspective, the Correspondence Analysis suggested that major gains might derive from a strategy that moved Heublein into more direct competition with Brands H, L, and N. These brands were regarded by both management and consumers as a separate product category. Their very heavy consumption derived from a wide range of usage situations which offered little volume usage individually, but a major opportunity cumulatively.

Approaches that might reposition the Heublein brand against new usage contexts were explored by superimposing attribute ratings data on the map shown in Figure 4. The resultant map suggested several approaches that could contribute to a more effective defensive positioning, including attention to those attributes where competitors' users perceived Heublein's brand to warrant improvement. A different set of considerations seemed relevant to expansion into new high volume opportunities.

Market Simulation

While the Immediate Category Study had revealed some defensive needs and some possible approaches to a heavy user strategy, it had also suggested that a successful strategy would probably require a number of mutually supportive elements. The Total Market Perceptual Study had reinforced these findings, and furthermore suggested that longer term expansion might imply different actions than shorter term defense.

In a traditional market study, these results would have concluded the project. Furthermore, the study would have been deemed a success in research terms, since it had hypothesized several promising directions for management consideration. However, in our view, data analysis — even sophisticated multivariate analysis — is not sufficient to address management concerns. As a case in point, the analyses in the current study had not provided a firm basis for evaluating alternative strategies, or for assembling them into coherent marketing programs. If it is to be truly actionable, strategic research must proceed one step beyond data analysis, and use other approaches to provide definitive statements regarding the corporate implications of each strategic possibility.

The methodology used for this study made such a next step possible. Through micro-behavioral simulation, it offered the ability to evaluate a virtual infinity of possible strategies. This simulation capability was an especially powerful feature of the research program, enabling broad directional hypotheses to be translated into specific action plans that could be acted upon directly.

The technical details of SCIMITAR's simulation approach are beyond the scope of the current paper, and are dealt with thoroughly elsewhere (see Beazley and Westwood, 1976, Palmer and Westwood, 1976). We shall therefore make only a few general explanatory remarks.

The SCIMITAR simulation model is a planning tool that tests strategic ideas through "what-if questions" addressed to a data base held within the computer. The user can create new brands, delete brands, and change brand perceptions inside the computer, which provides estimated results in terms of share potential, target group, and source of business.

Internally, the model operates by first "imitating" the ways in which individual respondents make brand choices, then aggregating individual responses into estimates of market potential. The simulation of individual respondent choice is based on the integration of brand image and utility data through a series of "decision rules" that replicate simple human thought processes:

1. Which brands is the respondent aware of?
2. Do any brands have completely unacceptable characteristics? (If so, reject them.)
3. Is any remaining brand unique in having an advantage on any important attribute? (If so, accept it as the predicted choice.)
4. Are any remaining brands inferior on the most important screening criterion; the second; and so on? (If so, screen them out of the set under consideration.)
5. What is the total utility associated with the attributes of each remaining brand? (Select brand with highest utility.)

Simulation runs were used to test the implications of a wide variety of image changes — first on single attributes, then on several attributes together. The results of some of the simulations based on single attributes are shown in Table 3.

TABLE 3
SIMULATION OF THE EFFECTS OF
UNIDIMENSIONAL BRAND IMAGE CHANGES

	Heublein brand	Major competitor
INITIAL SHARE	32%	17%
SINGLE ATTRIBUTE CHANGES		
A. Portion size	35%	16%
B. Consistent texture	35%	16%
C. Good value	35%	16%
D. Modern package design	36%	15%
E. Wholesomeness	36%	15%
F. Enjoyed by children	37%	15%
G. Good by itself	38%	16%
H. Low fat content	38%	16%

Several of the simulated changes replicated strategies that had previously been test marketed, and the results accorded well with the company's experience. As is customary in SCIMITAR projects, the simulation model had already been validated internally in terms of its ability to reconstruct the current brand choices of individuals interviewed, with satisfactory results. But the external validation against historical events, was, perhaps, a more

profound test of the model, and the management credibility it generated was of great assistance in implementing the model's recommendations concerning new strategic possibilities.

Simulation results provided clear confirmation of one of the major hypotheses previously emerging from data analysis, showing that Heublein's competitive position would not be improved dramatically by an isolated action on any single market dimension. In passing, we might note that this is by no means a typical result from the model, which often identifies individual attributes with significant competitive power (see, for example, Colvin, 1976, Gunter and Beazley, 1976).

Since no single attribute changes provided promising market potential, the simulation model was next used to test various attribute combinations that could be assembled within a brand strategy. Table 4 displays the results of some of these simulation runs.

TABLE 4
SIMULATION OF THE EFFECTS OF
MULTIDIMENSIONAL BRAND IMAGE CHANGES

	Heublein brand	Major competitor
INITIAL SHARE	32%	17%
MULTIPLE ATTRIBUTE CHANGES		
A + B + C + D	49%	8%
E + F + G + H	53%	9%
A + B + C + D + E + F + G + H	61%	6%

It was apparent that, although strategies based on single attributes were unlikely to be effective, certain combinations of attributes appeared to offer sizeable opportunities. This, of course, was a major finding in its own right, stressing the need for management to move away from individual tactical changes, and towards an integrated program of strategic activities.

More specifically, the model was able to point to the particular combinations of actions that would be expected to maximise market impact. For example, rectification of the defects that had been found in the brand's image among competitors' users was shown to offer good results, especially if incorporated with certain new benefits.

Simulation produced particular dramatic findings regarding overall business development, revealing that it was possible to merge shorter and longer term objectives within a single brand plan. Some of the attributes relevant to expansion beyond the current competitive frame were also found to be powerful within the more narrowly defined immediate category, provided that they were made part of a broader program.

Thus, through its use of market simulation, Heublein was able to develop a coherent multi-component strategy, that could be phased over time in a way that would build progressively more impact on the market. Early strategic phases would be concerned primarily with defensive considerations within the brand's immediate product category. These early phases, however, would pave the way for subsequent actions that would expand the brand's competitive horizons, and create the preconditions for new growth.

Conclusions

Although we have necessarily simplified and disguised this case history, we hope that we have communicated its considerable value to Heublein's strategy development.

For the future, we anticipate that Heublein's strategic research will continue to be firmly centered on consumer decision processes, and that attention will broaden beyond the issue of brand choice to embrace the full set of decisions that consumers make — including whether or not to purchase a category, how often to purchase it, and so on. This behavioral focus seems to us to be the natural and proper approach to strategy, since all marketing actions seek ultimately to influence consumer decisions in one respect or another. The recent advances in Information Processing Theory offer a framework, and to some extent a set of methodologies, that are suited to this purpose.

Furthermore, we expect that micro-behavioral simulation will continue to feature prominently in Heublein's attempts to understand how it can influence markets. Simulation promises to take research an important next step in its progress from description to explanation and eventually to prediction. It produces results in a form that is definitive, rather than vague and ambiguous, a form, furthermore, that is readily understood and implemented by management. Most importantly of all, it enables the strategy designer to move beyond the bounds of the problem at hand to a wider exploration of the multiple issues facing a brand in the real world.

A CONSUMER BASED APPROACH FOR ESTABLISHING PRIORITIES IN
CONSUMER INFORMATION PROGRAMS: IMPLICATIONS FOR PUBLIC POLICY¹

Rohit Deshpande, University of Texas at Austin
S. Krishnan, Pennsylvania State University

Abstract

Although there exists substantial research on the style and format of consumer information programs, little attention has been devoted to the critical issue of whether consumers need new information at all. A conceptual approach to systematically assess this information need is described along with an empirical operationalization of the approach using data gathered from a sample of elderly consumers. Implications of this approach are discussed for public policy makers with suggestions for further research in the area.

Introduction

The past five years have seen an increasing amount of research being devoted to the public policy implications of consumer decision making. Paralleling the growth of this work has been a woeful disregard of the usefulness of the research in the actual policy making process. There have been some exceptions to this rule (Permut 1979), but consumer researchers have largely used a product orientation in their work, devoting themselves to tasks such as experimenting with different information presentation formats without undue emphasis on whether consumers desire the information at all. The result has been a subscription by both policy makers and marketing managers to a "more information is better" philosophy which has produced its obvious consequences discussed in the recent research controversy over information overload (Jacoby, Speller, and Kohn 1974, Russo 1974, Scammon 1977).

The dilemma has been recognized for some time now (Thorelli, Becker, and Engledow 1975); but, as McEwen (1978) notes, the suggested solutions stress what marketers or policy makers can do rather than what consumers need. The failure to use a marketing concept has produced information programs looking for people to use them. As Capon and Lutz (1979, p. 59) indicate: "Heretofore, policy makers have introduced consumer information programs without a clear idea of whether the particular information in the programs was desired by consumers."

The problem becomes even more serious when one considers the current trend toward reduced governmental involvement in regulatory and information providing capacities. Recent criticism of the FTC can be traced to feelings (within and outside government) that regulatory agencies are involving themselves in areas where no intervention was required. Clearly, there is a need to assess consumer desire for additional information or other support before programs are mounted to achieve this purpose.

Further, public agencies are similar to private organizations in that limited resources of money and manpower exist. The allocation of these scarce resources among information programs implies the establishment of a set of priorities. To use the Capon and Lutz (1979) analogy,

¹The authors wish to thank Dr. Gerald Zaltman and the University of Pittsburgh for providing the data for this study, and D. Sudharshan for his assistance. The research was supported by Administration on Aging, U. S. DHEW, Grant No. 5-38131.

if consumer information programs are looked at as products (or services), public policy makers can develop marketing programs detailing the alternative mixes of distribution, pricing (costing), and promotion. They also must decide which programs will be most effective.

Every marketing program begins with decisions on the market segment to which the product or program will be targeted. The development of the product itself lies in the predetermined need for that product by intended consumers. It is only after the determination of this need that the development of the product can be considered.

The discussion of this paper describes a consumer need based approach for deciding which products and services should be focused upon for consumer information programs. This approach is then operationalized for a specific segment of consumers, those over 64 years of age. Finally, the policy implications of using this approach are described by relating it to other current research in the area.

Conceptual Framework

The first task in the policy development process is to decide on a group of individuals to whom further information regarding products and services may be provided. Recent work in marketing literature suggests that the elderly (chronologically defined as over 64 years in age) are such a group. The lack of much empirical work describing the consumption habits of the elderly (Phillips and Sternthal 1977), their apparent disadvantages in the marketplace (Waddell 1975, Zaltman et al. 1978, Bearden et al. 1978, Deshpande and Krishnan 1979), and the growth of this age cohort as a proportion of the total U. S. population could be used as criteria for the selection of this consumer segment. These criteria are offered as illustrations, and several more could be developed to choose a target audience.

The next stage is an important one. Since information programs about a plethora of products and services cannot be practically developed (or even be needed), some method is required to determine the relative information demand for different products and services. One approach to determining this demand is obviously based on the perceived consumer need for information about a product or service. However, from an information program designer's perspective, this would be incomplete without a consideration of information availability. If consumers need certain kinds of information to make purchases, but this information is not difficult for them to acquire, then this is clearly not as critical a niche for program development as where both the need exists and the information is unavailable.² This may be called "information deficiency." When the degree of felt need for information for a product/service is high, as well as the difficulty in obtaining that information is high, a large information deficiency exists. Figure 1 shows an example of a scaling approach that can be used to describe an Information Deficiency Index for a product/service category.

²Both information need and availability were identified by elderly consumers during preliminary focus group interviews as being of major importance to them in making purchase decisions.

FIGURE 1
Information Deficiency Index* Scheme

		PERCEIVED NEED FOR INFORMATION ON PRODUCT	
		Yes	No
INFORMATION DIFFICULT TO OBTAIN	Yes	INDEX = 3**	INDEX = 2
	No	INDEX = 2	INDEX = 1

*Information Deficiency scores are unique only up to an ordinal level.

**Most critical niche for information program development.

On this index, it is assumed that the two dimensions (perceived need and difficulty in obtaining information) have equal weighting. This assumption has been made for lack of additional empirical information, although any alternative weighting scheme would as well be reflected in the indices given to each cell.

Information Deficiency scores for a set of "relevant"³ products and services can be developed using the above scheme. However, an approach is required for comparing the relative magnitudes of information deficiencies for different products for the consumer segment being considered. This implies that a method for interpreting the ordinal measurement in interval scale terms is needed. A procedure enabling this is the Thurstone Case V scaling model (Thurstone 1959), an excellent marketing application of which is described by Green and Tull (1978, pp. 180-87). The use of this model is provided in an empirical illustration below that follows the description of the sample used for this study.

Sample and Data

Data used in this study come from a larger research program focusing on the consumer problems of the elderly. The program investigates, among other issues, susceptibility to misleading marketing practices, information processing, and restitution mechanisms. Two structured mail questionnaires were developed from focus group discussions on these issues. The questionnaires were mailed six months apart to a national panel of 4,000 persons aged 25 to 80. The response-rates for each wave of the survey were 71.3% (2,853 responses) and 89.4% (2,551 responses from first-wave sample), respectively. In comparison with available statistics on the national level (U. S. DHEW 1978), the following were the characteristics of the overall sample:

- (1) a (naturally) disproportionate proportion of individuals over age 64 (61% to 11% nationally),
- (2) a lower representation of blacks and hispanics (3% and 0.1% versus 8% and 4% nationally) respectively,
- (3) a slight underrepresentation of high school graduates and a modest overrepresentation of college graduates, and
- (4) fewer individuals whose spouses were no longer living.

The analysis discussed in this paper deals with 1,747

³ A context specific definition of "relevance" is provided in the next section.

usable responses from the elderly (over 64) subsample or 68% of the final sample.

In the first wave of the questionnaire, respondents were presented with a list of over 40 products/services and asked to indicate those where they had felt cheated or taken advantage of during recent purchase experiences. This "bad buying experience" question also had an open-ended provision for products not included in the list (the original list had been arrived at through earlier focus group discussions). Table 1 presents the incidence of bad buying experiences as reported for the above question for the more frequently cited experiences.

TABLE 1
Bad Buying Experiences Reported
(Elderly Subsample, N = 1,163)

**Appliance Purchase/Repair	(28.8*)
**Home Repairs	(21.7)
**Insurance	(21.4)
**Auto Repair	(19.7)

Pictures Taken at Store	(5.8)
Clothing	(5.4)
Landlord/Tenant Arrangements	(5.0)
Contractors/Builders	(4.9)
Investment Opportunities	(4.6)
Vacation/Travel Services	(4.5)
Contracts/Signed Papers	(4.0)

*figures in parentheses are percentages.

**major problem incidence areas.

After consultation with an advisory council of experts and policy makers in the elderly area, products and services with the most frequent citations in the above list were selected for more intensive scrutiny. These were (1) auto repair, (2) auto purchase, (3) home repair/improvement, (4) utility services, (5) insurance, (6) health care, (7) non-medical professional services, (8) appliance purchases, and (9) appliance repairs.

In the second wave of the study, the following question was asked:

I've listed below some different types of products or services. In Column A, "X" all those where you feel that you, personally, need information. In Column B, "X" the products or services where you feel the information you need is difficult to get.

	Column A Need Information	Column B Information Difficult To Get
Auto repair	<input type="checkbox"/> 1	<input type="checkbox"/> 1
An auto purchase	<input type="checkbox"/> 2	<input type="checkbox"/> 2
Home repair/improvement	<input type="checkbox"/> 3	<input type="checkbox"/> 3
Utility services	<input type="checkbox"/> 4	<input type="checkbox"/> 4
Insurance	<input type="checkbox"/> 5	<input type="checkbox"/> 5
Health care	<input type="checkbox"/> 6	<input type="checkbox"/> 6

	Column A Need Information	Column B Information Difficult To Get
Non-medical professional services	<input type="checkbox"/> 7	<input type="checkbox"/> 7
Appliances, purchase	<input type="checkbox"/> 8	<input type="checkbox"/> 8
Appliances, repair	<input type="checkbox"/> 9	<input type="checkbox"/> 9

The data obtained from 1,747 elderly consumer responses to this question form the basis for subsequent analysis reported below.

Analysis

For each respondent, an Information Deficiency (ID) score was determined as per the index described in Figure 1. Table 2 shows the median scores for each of the nine product categories being considered. Although these median values give some indication of the extent of information deficiencies present, as mentioned earlier, they still do not permit a meaningful comparison of the differences in relative magnitudes of the deficiencies for different product categories. This implies that the median values simply indicate that the information deficiency is greater for appliance repair than for home repair/improvement with no indication of how great the relative deficiency is. To do this, the ID scores can be converted using the Thurstone Case V model.

TABLE 2
Median Information Deficiency Scores

1. Auto Repair	1.584
2. Auto Purchase	1.246
3. Home Repair/Improvement	1.761
4. Utility Services	1.380
5. Insurance	1.359
6. Health Care	1.396
7. Non-medical Professional Services	1.477
8. Appliance Purchase	1.228
9. Appliance Repair	2.494

(N = 1,747)

This model is developed by first calculating the proportion of respondents for whom the ID score is higher for product category "j" than for category "k" for all possible category pairs. This is denoted by (j,k). The proportion of respondents having equal ID scores for a given category pair (j,k) were divided equally between proportions for (j,k) and (k,j). Table 3 shows the proportions matrix that results. For example, the entry in the second column and first row indicates that 37.8% of elderly consumers had a higher ID score for product category #2 (Auto Purchase) than for product category #1 (Auto Repair).

TABLE 3
Observed Proportions Matrix

		Product Category j								
		1	2	3	4	5	6	7	8	9

1. Auto Repair
2. Auto Purchase
3. Home Repairs/Improvement
4. Utility Services
5. Insurance
6. Health Care
7. Non-medical Professional Services
8. Appliance Purchase
9. Appliance Repair

*Table to be read as:

37.8% of respondents have a higher ID score for category 2 (Auto Purchase) than for category 1 (Auto Repair).

The Thurstone Case V model can be expressed simply as,

$$R_j - R_k = Z_{jk}$$

where $(R_j - R_k)$ is the relative distance expressing how much individuals discriminate between stimulus "j" and stimulus "k." In our case, this discriminial difference is the relative distance between the Information Deficiency for product category "j" and that for category "k." Also Z_{jk} is the standard variate (unit normal) associated with the observed proportion of cases in which the ID for "j" is perceived to be higher than that for "k." The model above assumes homogeneous perceptions of the stimuli across the respondent population. This assumption is supported to some extent in the split-half reliability test discussed below.

Table 4 reports the Z_{jk} scores matrix where each cell entry is the standard Z_{jk} variate associated with the corresponding entry in the Table 3 matrix (for computational procedure cf. Green and Tull 1978). The Thurstone Case V interval scale value (Information Deficiency) for each product category is then computed as the mean (\bar{Z}) of the column scores of the Z_{jk} matrix. Since this scale is unique up to an interval level, the ID values for the nine product categories can be rescaled with the lowest value (-0.254) being arbitrarily set to zero and the other values being correspondingly adjusted (R^*). Figure 2 expresses the rescaled ID values for the nine product categories on a unidimensional scale.

Discussion and Implications

As can be seen from Figure 2, the use of the Case V Approach provides a pictorial display of the Information Deficiency for different product categories. Since this is an interval scale, it can be used in a variety of manners for resource allocation in designing information programs. For example, we know that the difference in information deficiency between Appliance Repair and Non-medical Professional Services is approximately 4.8 times the difference between Non-medical Professional Services and Home Repair/Improvement since:

$$(.595 - .352) = 4.8(.403 - .352)$$

This provides an indication of the comparative resource allocation that can be made on information programs dealing with these specific product categories. Similar estimates of allocation can be developed for each of the nine categories described by the elderly consumer segment as requiring policy attention. Clearly, this can be a powerful tool when, as is usually the case, resources are limited and must be apportioned carefully. If the budget for an information program is extremely tight, it may even be necessary to expend resources on only three or four out of the nine categories described here.

Use of the approach outlined above then establishes the relative information demand priority for consumers. In an ordinal sense, it can be seen that more attention needs to be given to information programs on appliance repair, home repair, and non-medical professional services than, for instance, appliance purchase or automobile purchase at least as indicated by this sample of elderly consumers. More specific resource allocations can be determined using the pairwise differences rationale outlined above. Furthermore, other conceptual dimensions can also be used to determine information deficiencies or gaps. For instance, the cost of acquiring information and how understandable it is may replace the information need and availability dimensions used in our analysis.

As mentioned in the introductory comments, the use of this approach is based on consumer need for information rather than policy maker determinations of what information to provide to whom. It is possible that the use of such an approach can forestall both the criticisms of policy intervention where no intervention was desirable and that of consumers being provided with more information than they can efficiently process before making purchase decisions.

The conceptual approach suggested also has the advantage of allowing the comparison of different consumer segments

which need information-program attention. For example, it is conceivable that other demographic groups besides the elderly may need information regarding appliance and home repair. It may then be more cost-effective to devise programs targeted at all of these groups with similar information needs.

Conclusion

It remains to tie in the approach suggested here to some of the literature on public policy implications of consumer decision making referred to earlier. Responding to criticisms that research in consumer decision making takes an overly product orientation (McEwen 1978, Thorelli et al. 1975), this paper had advocated starting by focusing on consumer demand for information. In directly employing the marketing concept (Capon and Lutz 1979), policy makers would first select a target audience or segment and then determine what its information demands are (Day and Brandt 1974). This determination would be based on both information need and information availability dimensions. Additionally, it should allow policy makers to set priorities by product or service category.

Once these priorities have been set further research can be carried out to investigate the specifics of the information needed, such as unit pricing (Russo 1974) or restitution mechanisms for product complaints (Hunt 1977), and information presentation formats (Bettman 1975, Bettman and Kakkar 1977). But, to implement these latter information program specifics exclusively would be to deny the existence of consumer need for the program. This, in turn, would in all likelihood jeopardize the program in terms of its perceived relevance or usefulness to the consumers for whom it has been designed.

INFERENCE BELIEF FORMATION THROUGH THE USE OF
NON-INFORMATION: AN EXAMPLE

David W. Finn, Texas Christian University

Abstract

This paper reports on a surprising source of consumer information--the absence of information about salient attributes. This finding adds another dimension to research into the inference process. Not only do consumers combine information from the message, source, etc., to form beliefs, but they also seem to use information that is conspicuously absent.

Introduction

Perhaps the strongest single influence on consumers' behavior is the information they have about various choice alternatives--that is, the beliefs they possess about the alternatives on important dimensions. In fact, many attempts to model consumer behavior are structured around consumers' information and experience. For example, the Engel, Kollat, and Blackwell (1978) model discusses how information and experience are updated and changed (Information Processing), how information and beliefs are used to form attitudes and intentions toward alternatives (Product Brand Evaluations), and how existing levels of information influence the purchase process (Decision Process Stages). Similarly, the Howard-Sheth (1969) model places beliefs and brand experiences in crucial positions. Howard and Sheth offer explanations of how Perceptual Constructs mediate the effect of various inputs on beliefs (Brand Comprehension) and discuss how changes in beliefs related to brand knowledge and Choice Criteria influence attitude and intention. In summary, the central influence of beliefs on behavior is widely recognized.

If we accept these views that beliefs influence attitudes and intentions, and that attitudes and intentions, in turn, influence behavior, then the study of consumer belief formation and change becomes important in the study of consumer behavior. Three issues immediately present themselves regarding beliefs: 1) What are they? 2) What kinds are there? and 3) Where do they come from? The first two questions are handled rather easily. If all researchers can agree on a definitional basis for study, the explorational efforts into the third question will be more easily diffused.

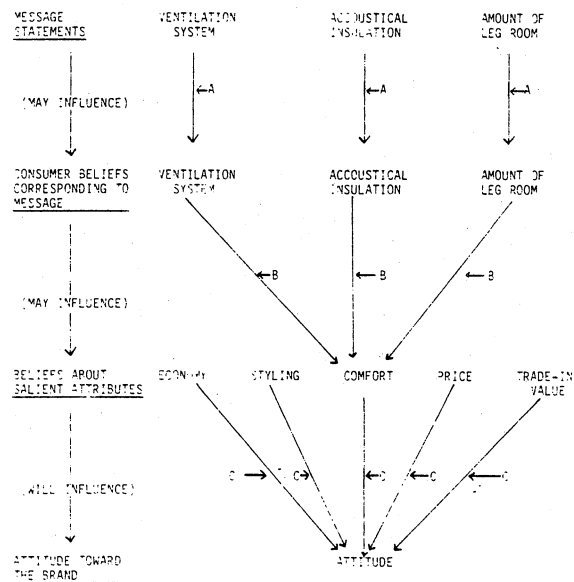

Fishbein and Ajzen (1975), in reviewing and condensing much of the literature related to beliefs and attitudes, have offered the definition of beliefs as representing the information a person has about an object. They further instruct that a belief can be expressed as a person's subjective probability that some object (or brand) has some specific attribute. This view of what beliefs are has built into it a method of measuring beliefs--namely via probabilistic scales.

They describe three basic kinds of beliefs, classified according to the informational determinants associated with belief formation. Beliefs formed as a result of direct observation and experience are called descriptive beliefs. A consumer forms descriptive beliefs about different brands mainly through use experience with them. For example, if a person test drives an automobile and feels the comfort and experiences the roominess, s/he will come to form beliefs about the presence or absence of these attributes. Predictably, beliefs formed in this manner are held with a great deal of confidence. Very little research has been

conducted on the nature or formation of descriptive beliefs although these beliefs are commonly tapped in various consumer behavior studies. Measures of recall, blind taste tests, and exploratory product concept tests all typically measure levels of consumer experience and preference that can be labeled "descriptive".

A second type of belief, one that is typically held with much less confidence, is an informational belief. Informational beliefs are formed by accepting information provided by an outside source. Most of the opinion formation literature, the literature on credibility and fear appeals, and other examples related to the work of the Yale group (Hovland, et al 1953), is concerned with the study of informational beliefs. In the consumer behavior literature, a study by Holbrook (1978) contains a clear example of informational belief formation. As is typical in message content research, Holbrook's study contained a message composed of belief statements related to the target beliefs that the message was meant to influence. For example, Holbrook listed characteristics of an automobile ventilation system, its acoustical insulation specifications, and its amount of leg room in order to influence receivers' beliefs about the comfort and roominess of the car in question. Clearly, before any change can take place in the target belief (comfort), the listener must first accept or reject the information about the ventilation system, etc. Belief links "A" in Figure A represent the location of this informational belief influence. The degree to which this information is accepted depends, in part, on the source, message, and channel performing the communication.

FIGURE A
ANTICIPATED INFLUENCE CHAIN FROM HOLBROOK (1978)

The third belief type is an inferential belief. Inferential beliefs are formed through the process of utilizing previously learned relationships. In the example above and in Figure A, consumers were expected to form beliefs about the comfort of the car based on their previous experience and knowledge that the ventilation system, insulation, and amount of leg room were all different aspects of the overall comfort of the vehicle. The message itself did not mention comfort, and formation of a belief that the vehicle is comfortable depends both on the level of acceptance of the message statements (informational belief formation) and on the inferences that receivers draw about the relation between comfort and these three attributes. (links "B" in Figure A). A successful change in this target belief will influence a consumer's attitude toward the car if comfort is a salient attribute. Figure A illustrates the influence links between message items and attitude.

Much of the knowledge we have of the inferential belief formation process is related to the literature on trait inferences started by Asch (1946). One of the more promising directions this literature has taken is toward the measurement of probabilistic relationships among beliefs--not only those beliefs related to message content, but also those beliefs residing in memory that can influence further belief formation. An early study of these probabilistic relationships is McGuire's (1960) analysis of logical syllogisms. Further work has been done by Wyer (1970; Wyer and Goldberg 1970), and an excellent positioning of this literature into the realm of consumer research was offered by Olson (1978). The Holbrook study is an important step in measuring these relationships in a consumer behavior setting.

Impact Effects

Not all inferential beliefs are formed due to planned influence by a communicator. Sometimes listeners take information from the communication and combine it with previously learned material in a completely unexpected manner. The result is inferential belief formation due to an unexpected impact effect. A good example of an impact effect is found in the corrective advertising study by Mazis and Adkinson (1976).

In their study, Mazis and Adkinson compared the effects of four different advertising messages about a brand of mouthwash. Three of the messages contained a germ killing appeal, while two added a corrective statement that "colds and sore throats could not be prevented, cured or benefited" by the use of the brand. Additionally, the corrective versions varied by apparent source of the corrective statement. The messages were:

- 1) noncorrective copy with germ killing appeal,
- 2) FTC required corrective copy with germ killing appeal,
- 3) corrective copy with germ killing appeal (no source mentioned), and
- 4) noncorrective copy with no germ killing appeal

All four versions made claims about the brand's usefulness in preventing bad breath. Version #1 differed from version #4 by also emphasizing the brand's germ killing ability. Version #3 differed from #1 only in the additional corrective copy that the brand could not prevent colds and sore throats. Finally, advertisement #2 added the phrase, "The previous statement was required by the Federal Trade Commission." This systematic inclusion of additional message statements allows us to measure belief change as influenced by incremental information. Table 1 repeats a portion of the Mazis and Adkinson data. Since Mazis and Adkinson found no difference in beliefs between messages 2 and 3, message #2 is deleted.

TABLE 1
BELIEF MEANS AND STANDARD DEVIATIONS
FOR EXPERIMENTAL ADVERTISEMENTS^a
[From Mazis and Adkinson (1976)]

DEPENDENT VARIABLES (Beliefs)	GERM KILLING NON-CORRECTIVE (Ad #1)		GERM KILLING CORRECTIVE (COMPANY) (Ad #3)		NON-GERM KILLING NON-CORRECTIVE (Ad #4)	
	M	SD	M	SD	M	SD
KILLS GERMS	1.42	.61	3.47	1.91	2.39	1.80
HELPS PREVENT COLD/SORE THROATS	2.16	1.74	4.67	1.83	3.04	2.01

^aBeliefs measured on seven-point probabilistic scales: "What is the probability that brand) has attribute)." "1" represented greatest amount of association (strong belief) and "7" represented smallest amount of association.

Comparing messages 1 and 4, we can isolate the effect of the germ-killing appeal. Because of the large difference in the sample variances, an approximation to the t-test must be used with an adjustment to the degrees of freedom (see Winkler and Hays, 1975 pg. 372). On a seven point scale (1 equals "probable", 7 equals "improbable"), the 23 respondents exposed to message #4 reported an average rating of 2.39 that the brand kills germs. The average rating for the 19 respondents exposed to message #1 was 1.42. The t-test approximation (28 d.f.) reveals that this difference is significant beyond the .025 level. In other words, the germ killing appeal, alone, had a positive influence. As expected, there is no significant difference on the "cold prevention" belief.

The influence of the corrective statement can be measured by comparing messages 1 and 3. Since they differ on only this piece of information, we should expect to see changes in only this belief. Table 1 reveals that this is not the case! Large and significant changes are present on the "cold prevention" belief (as expected), but large changes are also present in the "kills germs" belief. Introduction of the corrective statement had an unexpected impact on the belief that the brand kills germs.

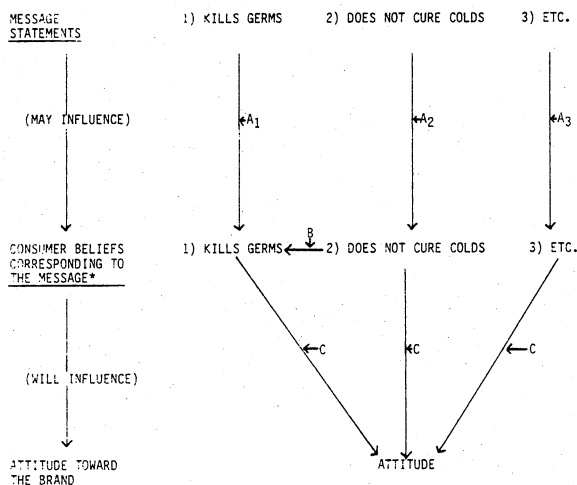

Even though message #3 emphasized the brand's germ killing properties, an audience exposed to it had significantly weaker beliefs that this was true than an audience exposed to the same message without the corrective statement (message #1). Figure B illustrates what may have happened:

- 1) as shown in Figure B, the germ killing emphasis of the message positively influenced receivers' beliefs that the brand kills germs (link "A1" of Figure B and the comparison of messages 1 and 4) while the corrective statement positively influenced their belief that it does not cure colds (link "A2"); and
- 2) the belief that the brand does not cure colds was inferentially related to the belief that the brand kills germs and impacted negatively on that belief (link "B" of Figure B).

Depending on the relative sizes of the positive and negative influences, the resulting "kills germs" belief could be stronger, weaker, or the same as the "kills germs" belief of an audience exposed to only message #4 (no mention). However, because of step #2 above, we would expect every audience exposed to message #3 to have weaker beliefs that the brand kills germs than an audience exposed to message #1. The Mazis and Adkinson data support this idea.

This example of an unexpected impact effect emphasizes the need for understanding the experience and belief systems of potential consumers before directing persuasive

FIGURE B
APPARENT INFLUENCE CHAIN FROM MAZIS AND ADKINSON (1976)

*Although Mazis & Adkinson did not isolate these particular attributes as salient, illustrating them as such will serve to demonstrate a two link chain from message to attitude.

communications at them. Where the Holbrook study showed that certain inferential processes can be expected, the Mazis and Adkinson paper can be interpreted as warning that inferential relationships can work against the intentions of the communicator. Both of these analyses demonstrate inferential belief formation due to the interaction between previously learned relationships and message-related beliefs--one planned and one unplanned. It is a logical step to expect that inferential beliefs might also result from an interaction between previously learned relationships and perceptions of the communication source or channel (e.g. one learns the characteristics associated with "trust" and forms message-related beliefs that vary in strength depending upon how the source matches those characteristics). We might conclude that the inferential process can distort any message-related belief or can use message-related beliefs in combination with any other learned material to create new beliefs. This logic, however, does not lead to any predictions concerning the absence of information. This paper presents evidence that impact effects resulting from the inference process can also occur in situations where certain information (particularly about salient product attributes) is totally absent.

Procedure

Two hundred and thirty-one junior and senior business students at a large Northeast university participated in the study. A posttest-only control group design was used (Campbell and Stanley, 1963), with one hundred and one of them serving as a control group. The others were exposed to an advertising-like message about a fictitious brand of toothpaste. The cautions voiced by Ferber (1977) were exercised in choosing the experimental product. The main consideration that guided the choice of the product was that subjects should have use experience with it and be the ones to make purchase decisions for it. Toothpaste was the ideal choice.

The use of an unknown brand was necessary because the study was concerned with belief change. Since beliefs about a brand are a function of information a person has about that brand, using an unknown brand allowed the assumption that the initial, or pre-exposure beliefs of both the control group and the experimental group were based on the same

information (little or none). Belief change could then be computed from the control group's position.

Accordingly, a cover story was invented that stated that a local professor (named) was engaged in consulting with a well known market research company (named) that specialized in test-marketing. The brand was said to be manufactured by a large, well known manufacturer (named) and to be in test market in the Mid-West. The members of the control group were told that the purpose of the questionnaire was to find out what their beliefs were concerning the new brand of fluoride toothpaste -- without any other information. They were to answer the questions using their knowledge and expectations about toothpaste in general.

After the cover story, the experimental group was told that the consultant had access to advertising information and that they were about to be shown the voice script of a television advertisement for the toothpaste. They were allowed to read the script (the experimental treatment) as many times as they wanted, but were not allowed to return to it once they started to answer later questions. The belief questions were the same as the control group's. The message is printed as Table 2.

TABLE 2
THE EXPERIMENTAL MESSAGE

VOICE SCRIPT OF A 30-SECOND TELEVISION ADVERTISEMENT FOR VISTA TOOTHPASTE

OFF-CAMERA VOICE: HEAR WHAT DOCTOR JOHN HUNT, A PRACTICING DENTIST IN CLEVELAND, OHIO, HAS TO SAY ABOUT NEW VISTA TOOTHPASTE.

DR. HUNT: HI! I'D LIKE TO TELL YOU ABOUT A NEW TOOTHPASTE CALLED VISTA. VISTA IS MADE WITH A NEW TYPE OF FLUORIDE. BUT IT'S NOT JUST ANOTHER FLUORIDE TOOTHPASTE.

THE FLUORIDE COMPOUND USED IN VISTA MADE IT POSSIBLE FOR (COMPANY) TO OFFER YOU A BETTER DECAY PREVENTIVE TOOTHPASTE THAT IS LOWER IN ABRASIVES, YET HIGHER IN WHITENING ABILITY, THAN OTHER BRANDS OF FLUORIDE TOOTHPASTE.

I REALLY LIKE THE TASTE OF VISTA. AFTER BRUSHING WITH VISTA MY MOUTH FEELS CLEAN. BEST OF ALL, WITH VISTA BOTH FRESH TASTE AND CLEANER TEETH ARE POSSIBLE, AND YOU DON'T HAVE TO SACRIFICE DECAY PREVENTION.

TRY VISTA

To measure subjects' beliefs about the brand, questions were asked about the probability of the brand being associated with various attributes. A seven-interval scale anchored by the phrases "very improbable" (1) and "very probable" (7) was used to record the response. Changes due to the message were measured from the control group mean.

TABLE 3
MEAN BELIEF CHANGES FROM CONTROL GROUP MEANS

DEPENDENT VARIABLE	CONTROL GROUP MEAN N = 101	CHANGE	SIGNIFICANCE ^a
MADE WITH NEW TYPE FLUORIDE	3.01	1.300	<.001
PREVENTS CAVITIES BETTER	3.63	-.080	NS
LOWER IN ABRASIVES	4.11	.453	.028
HIGHER IN WHITENING ABILITY	3.92	.402	.064
MAKES YOUR MOUTH FEEL CLEAN	5.49	-.139	NS
FRESH TASTE AND CLEANER TEETH	4.62	.253	NS
WORKS LIKE A MOUTHWASH	4.25	-.356	.080
SEAL OF APPROVAL	5.54	-2.391	<.001
ABOUT THE SAME PRICE	5.73	-1.153	<.001

^a Significance was computed using a two tailed t-test comparing control group to experimental group.

An earlier questionnaire had revealed that the salient attributes of toothpaste desired by members of the subject pool included; fluoride content, cavity prevention, low abrasiveness, whitening ability, good taste, the seal of approval of the American Dental Association, and a "reasonable" price. Many of these attributes were specifically claimed by the advertisement (Table 2) but no mention was made about the price or the seal of approval. It was expected that any message effects would be only on beliefs about those attributes specifically mentioned in the message (the "A" links) or on beliefs that could be inferentially linked to message content (for example, the "clean mouth" and "good taste" claims in the advertisement could result in a belief about "mouthwash effect"). Table 3 lists the beliefs measured. The beliefs above the dashed line are directly related to message elements; beliefs below that line were not contained in the message, but were measured to study possible impact effects.

Results

The results of the analysis are contained in Table 3. The first belief (made with a new type of fluoride) was the belief most dramatically affected by statements in the message. The control group (with no information) had an average belief of 3.01 on the seven interval scale. Members of the treatment group increased their belief to 4.31 on this ($P < .001$). Other changes in message related beliefs were less dramatic with only the third and fourth beliefs changing significantly.

Although changes in these early beliefs in the change chain from message to attitude would be necessary if targets lower in the chain (e.g., attitudes) were expected to change, the focus of this paper is on changes in beliefs not related to the message. The belief that the brand "works like a mouthwash" probably is inferentially related to message beliefs, and changes in it can be expected through the same processes as in the Holbrook paper. The last two beliefs however, appear to be unrelated to any message elements, yet change in them was among the largest of any belief changes. The message said nothing about the presence or absence of the seal of approval of the American Dental Association, yet the treatment group had a significantly weaker belief in its presence than the control group. A similar result is evident in the belief that the brand sells at about the same price as other brands.

Observation of the control group means revealed that, based simply on their past experiences with the toothpaste category, respondents had a fairly high expectation that any new fluoride toothpaste would possess the seal of approval and be priced in a competitive range. Unexpected impact effects of the message or the message environment changed these beliefs in a negative direction. Respondents exposed to the message did not report these strong beliefs.

Summary and Conclusions

The intent of this paper is to report on an interesting observation of impact effects of an advertisement. Other impact effects may be present, but to discover all of them, a complete inventory of beliefs would have to be measured - an impossible task.

Where did the large negative changes in beliefs about the seal of approval and price come from? Earlier in the paper it was demonstrated that impact effects occur on beliefs related to informational items in a message. It is very doubtful that "seal of approval" and "price" are related to informational items in the toothpaste message. However, it can be argued that they are related to information contained in the complete message environment. That is, the information processed by the treatment group included the observation

that nothing was said about these two salient attributes. If this is the case, then the schema proposed by Olson (1978) is applicable to non-information as well as to information. That is, the absence of any mention of "seal of approval" or "price" may have been perceived as a "cue" in the task environment, leading to the formation of a descriptive belief ("nothing was mentioned about ____"). This belief could then have combined with the expectation that a company would mention the attribute if the brand had it, resulting in an inference that the brand might or might not possess the attribute. Unfortunately, the results of this study were neither predicted nor expected, due to its exploratory nature, and the data were not collected in a manner that allows quantifying the possible relationships among beliefs. A tentative hypothesis is that "top of the mind" salient attributes are noticed in their absence as well as when mentioned.

The general findings of this study suggest the need for future research in at least two areas. First, what are the dynamics of inferential belief formation due to advertising? Holbrook (1978) attempted to explore this issue and has provided a meaningful framework for further study of the problem; the work of Mazis and Adkinson (1976) highlights the existence of unexpected impact effects related to inferential belief formation; and this study suggests that impact effects may result not only from the interaction of message elements, but also from the entire message environment.

The second area for future research evolves from the question, do consumers expect an advertiser to state product claims for those salient attributes for which he can make legitimate claims? This question has implications for identifying the more salient attributes of different product classes. That is, it may be that belief change as noted above is a good index of relative salience of various attributes. For example, if consumers make stronger inferences about salient than non-salient attributes, we could systematically leave out mention of various attributes and note the effect on beliefs. Those beliefs changing the most when not mentioned in an advertisement would then be identified as most salient.

Together, these two questions raise the issue, "what is the information content of non-information?"

AN EXAMINATION OF INFORMATION PROCESSING TRAITS: GENERAL SOCIAL
CONFIDENCE AND INFORMATION PROCESSING CONFIDENCE

James M. Munch, The Pennsylvania State University
John L. Swasy, The Pennsylvania State University¹

Abstract

This paper reviews Wright's (1975) findings concerning the role of the information processing traits General Social Confidence (GSC) and Information Processing Confidence (IPC). This review concludes that Wright's findings were an artifact of the experimental procedure. Also this paper presents suggestions for future research concerning the role of information processing traits as factors influencing cognitive resistance to persuasion.

Introduction

The systematic examination of persuasive communication is of great importance to both the public and private sectors of our economy. According to 1980 projections, U.S. total advertising expenditures will surpass \$55 billion. The ability to increase the effectiveness of such expenditures rests upon understanding audience responses to persuasive communications.

Early research in persuasion typically focused upon the direct measurement of outcome variables (e.g., attention, recall, beliefs, attitudes). More recent efforts have taken a process-oriented focus in an attempt to achieve a greater understanding of persuasion. One common approach is based upon evidence that receivers of a persuasive message actively process and subvocally react to the message content (Greenwald 1968). Reports of these reactions have been termed cognitive responses and are believed to reflect the results of the receiver's information processing. One typical categorization of such responses distinguishes counterarguments and support arguments to the message claims and also derogations or attacks against the message source (Wright 1973). Furthermore, these reported thoughts have also been categorized according to their origin (i.e., thoughts which were restatements or reflections of a message statement, or thoughts which were "original" or developed by the receiver, independent of message claims) (Greenwald 1968).

Marketing and psychology studies have shown that frequency counts of these response categories, taken from receivers' reports of their thoughts during a message, are good predictors of subsequent message acceptance and attitude change. This predictive ability, as well as physiological evidence supporting the mediating role of subvocal responses in attitude change (Cacioppo, Sandman and Walker 1978), provides strong evidence that cognitive responses such as counterarguing may underlie persuasion outcomes.

Much theorizing and research have been directed toward understanding the antecedents of message-evoked thoughts.

This research was supported by a grant to John Swasy from the Center for Research, College of Business Administration, The Pennsylvania State University. The authors gratefully acknowledge the helpful comments from the ACR reviewers. All correspondence should be addressed to John Swasy.

Such differential response to persuasive message arguments has been attributed to: prior experiences (e.g., individual differences), differences in communications (e.g., source effects), and the social context (e.g., situational factors), (Eagley 1980). Research has been undertaken to examine such factors as the accessibility of various responses from long-term memory (Edell and Mitchell 1978), prior commitment on the message topic (Osterhouse and Brock 1970), response opportunity (Petty, Wells and Brock 1976) and message processing goals (Petty and Cacioppo 1979).

To date, however, there has been quite limited interest in research attempting to systematically examine these cognitive responses in relation to receivers' information processing traits. The only published article to address the relationship between receivers' information processing traits and cognitive responses is Wright (1975). The purposes of this paper are to position Wright's research within the framework of the existing personality research paradigms, to review Wright's findings and to suggest an alternative interpretation of his results. Additionally several suggestions for future research dealing with the study of information processing traits will be presented.

Fundamental Paradigms in Personality Research

The premise of the relative stability of personality variables represents one of the classic issues for debate in personality research. The purpose of this section of the paper is not to resolve the issue of stability in personality research. Rather, our attempt is to briefly examine three fundamental paradigms pertinent to this issue and to position Wright's conceptualization of General Social Confidence (GSC) and Information Processing Confidence (IPC) within this framework. The three paradigms to be reviewed are the situationalist, trait, and interactionist positions. For a more comprehensive discussion of these personality/stability issues see Epstein (1979).

Situationalist Position. The situationalists argue that behavior is determined almost exclusively by situational variables. This premise is based on three fundamental sources of evidence:

- (1) When behavior in one situation is correlated with behavior in another situation the results are extremely low--usually less than .30. Thus, Mischel (1968) notes, "A correlation of .30 leaves us understanding less than 10% of the relevant variance."
- (2) Analysis of variance results have demonstrated that the variance attributable to individual differences is usually much smaller than the variance attributable to the interaction of individuals and situations, Endler and Hunt 1968, 1969; Endler, Hunt and Rosenstein 1962).
- (3) Ratings of stability of personality by others have consistently overstated the stability of individuals across situations (Bem and Allen 1974; Jones and Nisbett 1971; Mischel 1968; Shweder 1975).

Trait Position. Trait theorists contend that the failure to find stable traits across situations is primarily due to inappropriate research procedures. A host of arguments are advanced to support such a contention, the more

compelling being:

- (1) The unit of analysis has not been adequately taken into account. What appears to be instability at a behavioral level of analysis may be stability at the trait level of analysis (Alker 1972; Bowers 1973). Stated differently, apparently unstable behaviors may be based upon relatively stable traits.
- (2) The use of moderate variables would consistently increase reliability coefficients (Alker 1972).
- (3) A failure to recognize that some people are more variable than others results in reporting generally low stability coefficients.
- (4) Stability in personality is mediated by an individual's cognitions; therefore, stability will only be found when ideographic (i.e., symbolic or graphic) procedures are used that take into account the subjective nature of perception (Alker 1972; Bem and Allen 1974; Bowers 1973; Mischel 1973).

Interactionist Position. Although the interactionist position does not resolve the issue of stability of personality, proponents of the interactionist position contend that the controversy between individual (i.e., trait) versus situation is meaningless, (i.e., behavior is always a function of the joint interaction of these variables.) Clearly, in any psychological situation the interaction of individuals and situations should account for more variance than either source of variance by itself. Thus it has been argued that an interactionist position should supplant both the trait and situationalist positions (Bowers 1973; Ekehammer 1974; Endler 1966; Endler and Hunt 1968).

As Epstein (1979) suggests, the situationalist position, trait position and the interactionist position are in fact all "correct" approaches to different problems. The situationalist focuses upon the general effects of situations over a sample of individuals. The trait theorist examines the consistency of behavioral tendencies in individuals over a sample of situations. The interactionist studies the behavior of people with certain attributes in situations with certain attributes.

The researcher's decision regarding which personality paradigm or conceptual framework to choose is thus dictated by the research purpose. Since Wright conceptualized General Social Confidence (GSC) and Information Processing Confidence (IPC) as "chronic" traits and examined these traits in four different reception environments, an interactionist position is presumed. Additional comments regarding the compatibility of Wright's conceptual framework with the measurement of that conceptual framework are presented in later discussion.

Wright (1975)

This section of the paper will briefly review Wright's hypotheses and methodology. The discussion will be limited to only those aspects most germane to the role of information processing traits. Following this overview, Wright's results will be presented and examined.

In his article, "Factors Affecting Cognitive Resistance to Advertising," Wright discusses:

- (1) the role of information processing traits, and
- (2) decision task involvement in audio and print message presentations.

The information processing traits under study were Information Processing Confidence (IPC) and General Social Confidence (GSC). Both GSC and IPC were conceptualized as "chronic" personal characteristics related to transsituational abilities and habits. More specifically, GSC was

regarded as one's degree of skill or self-confidence in assessing personal ability in coping with everyday problems (i.e., a characteristic which exhibits both social and cognitive dimensions). IPC was described as one's confidence regarding the ability to process information or think fast (i.e., a characteristic which is evidenced by quickness of mental reflexes or cognitive agility). It should be noted that both were self perceptions of one's ability and not necessarily equivalent to actual knowledge structures or processing performance levels.

The decision task involvement factor addressed a motivational determinant of a receiver's cognitive resistance to persuasion. Subjects in the "high processing involvement" treatment were informed they could expect to make a short-run decision about the product appearing in the impending advertisement. The relevance of this decision was emphasized in terms of their families, their own time and effort, and their personal finances. Subjects in the "low content involvement" treatment received no such information.

Wright's persuasive message treatment consisted of the presentation of either an audio or print advertisement. The audio message was defined to be a strainful information processing situation since subjects receiving the treatment had no control over the speed of message delivery or inflections of the speaker. Those subjects who received the print ad were by definition, engaged in a relatively leisurely information processing task.

Wright's Hypotheses

The focus of Wright's research was to address the form of the GSC-message acceptance relationship. Cognitive responses were also examined in order to test the hypothesis that people low in GSC might find it difficult to cope with both message encoding and critical message scrutinizing under strained processing conditions (i.e., audio mode) and therefore opt for source evaluation responses (e.g., source derogations) rather than message oriented responses (e.g., counterargumentation). Additionally, Wright introduced the information processing confidence (IPC) construct as an indicator of a person's mental reflexes.

Wright's hypothesized arguments regarding GSC and IPC are summarized as follows:

- (1) In a strained information processing environment (i.e., audio mode) both GSC and IPC will shape the nature of the responses. This can be contrasted with the unstrained (i.e., print) condition in which no strong relationship between GSC and IPC and message acceptance was expected.
- (2) In the audio presentation to a highly involved audience, a sense of social confrontation will be created. Therefore as in highly social situations, both GSC and IPC will be important determinants of a receiver's responses, however GSC will be relatively more important.
- (3) For audio presentations which reflect a less social confrontation (i.e., low involvement), both the GSC and IPC factors will again emerge, but those information processing capabilities (i.e., IPC) are posited to contribute more to individual differences in responses.

Figure 1 illustrates Wright's 2 x 2 crossed factorial design and highlights these hypothesized relationships.

Wright's Methodology

Subjects in Wright's study were 160 adult housewives. Each woman was randomly assigned to one of the four communication conditions in the 2 x 2 crossed-factorial design. A new type of food product (i.e., a soybean derivative) was chosen for the topic of the message to minimize product knowledge differences. The message arguments contained six favorable

FIGURE 1
Wright's 2 x 2 Cross Factorial Design and
Hypothesized Relationships

Task Involvement \ Media Mode	Audio Advertisement (strained information processing environment)	Print Advertisement (unstrained information processing environment)
High Involvement (high social confrontation)	Both GSC and IPC effect receiver's responses to the message with GSC > IPC	No relationships
Low Involvement (low social confrontation)	Both GSC and IPC effect receiver's responses to the message with IPC > GSC	No relationships

reasons for possible product adoption. In order to simulate as far as possible the natural conditions in which people encounter mass media advertising messages, Wright presented the ad following a short "editorial" statement. Immediately after exposure, cognitive responses were collected, followed by measures of message acceptance, content recall, and a check of the involvement manipulation. Subjects then rated each thought as "extremely important," "moderately important," or "slightly important." Also they rated each thought according to whether they felt it had originated directly in the message, had been a reaction on her part to an idea directly stated in the message text, or was an "original" thought in the sense that it was self initiated rather than a response to a direct statement in the message text (Wright 1975, p. 5). This thought judging task was then followed by a peer evaluation task² and the self report GSC and IPC measures. These are reported in Table 1.

Wright's Results

Wright's findings were generally consistent with the hypotheses presented above. The GSC and IPC scores were more highly correlated with counterarguing (CA) in the strained (i.e., audio) than in the less strained (i.e., print) conditions. As expected, for the audio presentation when involvement was low, the IPC-CA correlation was stronger than the GSC-CA correlation, while the GSC-CA correlation was stronger in the high-involvement audio condition. (See the selected results reproduced in Table 2). Wright also suggests that the same pattern (i.e., the flip-flop in importance for GSC and IPC) was observed for the trait message acceptance correlations.

Critique of Wright (1975)

A close examination of Wright's findings suggests that several conceptual and methodological issues need to be re-considered prior to the validation of GSC and IPC as information processing traits. This issues are:

- (1) Why did only the number of counterarguments classified by subjects as "original" evidence the hypothesized interactions with task involvement? and;
- (2) Is it appropriate to conceptualize GSC and IPC as "chronic" or enduring information processing traits and measure them in the manner used in this study?

² The peer-designated opinion leadership factor is not central to our analysis and will not be addressed in this review.

TABLE 1
General Social Confidence and Information Processing
Confidence Measures (Wright 1975)

- General Social Confidence
1. I do not spend much time worrying about what people think of me.
 2. It doesn't bother me to have to enter a room where people are gathered and already talking.
 3. When confronted by a group of strangers, my reaction is always one of shyness and inferiority.
 4. I am sure someday my companions will look up to me and respect me.
 5. I have frequently given up doing something because I thought too little of my ability.
 6. I feel capable of handling myself in most social situations.
 7. I don't make a very favorable first impression on people.
 8. I often fear my actions will cause other people to have a poor opinion of me.
 9. In group discussions I usually fear my opinions are inferior.
 10. I am not at all lacking in self confidence.

Information Processing Confidence

1. I have more trouble concentrating than most people.
2. I am able to solve riddles and puzzles rapidly.
3. My mind seems to work slowly compared to those around me.
4. I am totally confident about my ability to judge messages coming from the mass media.
5. I am certainly able to think quickly.
6. When I hear an argument being presented, I am quick to spot the weaknesses in it.
7. I usually have to stop and think for awhile before making up my mind even in unimportant matters.
8. My thoughts frequently race ahead faster than I can speak them.
9. I am never at a loss for words.
10. I don't seem to be very quick-witted.

Consistency of Results and Theory

The question of why only the number of counterarguments coded by subjects as being "original" counterarguments were related to personality traits can initially be discussed at a conceptual level. That is, one might have reasonably expected that the total number of counterarguments generated, irrespective of origin should have been related to these information processing traits. Indeed, as Wright suggests, prior theoretical discussions (Cohen 1958; McGuire 1969; Bither and Wright 1973) all imply that a negative linear relationship with counterargumentation and GSC and IPC should be expected. However these discussions do not address expected differences between "original" and other counterarguments' relationship to processing traits. Regarding this issue, the question also arises as to why the total number of thoughts irrespective of nature (i.e., counter or supportive) and origin should not be related to these information processing traits. Although Wright's premise suggests that individuals might hold a range of attitudes toward the content of a persuasive communication, existing theoretical and empirical evidence appears weak as to why the number of "original" counterarguments should be correlated more strongly than other cognitive response types with these personality traits. One plausible explanation for the resultant relationship between GSC, IPC and the number of "original" counterarguments may be the experimental procedure employed by Wright.

Methodological Considerations

This section of the paper attempts to address three important methodological issues in Wright's research:

- (1) The appropriateness of the data collection order.

TABLE 2
Selected Within Cell Correlations of GSC and IPC
With Response Measures (From Wright 1975)

^a p < .01

^b p < .05

^c Acceptance (A₁): "The arguments about the product contained in the advertisement were very convincing"

Acceptance (BI): "Will you purchase when it becomes available in your local area?"

Acceptance (Index): Weighted index of subject's reported thoughts (i.e., $\sum_k w_k SA_k - \sum_j w_j CA_j - \sum_k w_k SD_k$)

where w_j s are subjective importance weights of each thought assigned by the subjects.

- (2) The problem of interpretational confounding.
- (3) The measurement issue concerning the validity of the GSC and IPC scales.

Order of Data Collection. In Wright's study the subjects reported their thoughts directly following their viewing of the ad. They were then given the task of indicating the "origin" of each thought (e.g., "Was this an idea or reaction which reflected a point presented in the ad message or was this one of your own?") and then given the IPC and GSC measures. Since one normally conceives of personality traits as being CAUSAL determinants of cognitive responses, the order of measurement for these variables should have been consistent with this conceptualization.

In all likelihood the experimental treatment which subjects had just experienced created a mental framework or set which influenced their responses on the IPC and GSC measures. It appears evident that subjects who have just experienced a task which called upon them to assess whether or not their "thoughts" were their "own" (rather than a reflection of the speaker's) should respond consistently when asked questions regarding their skills in a social confrontation situation (i.e., How well they can spot a weakness in an argument?). That is, subjects who have indicated that each counterargument was "original" (and therefore have a large number of original counterarguments), should express a high degree of "social confidence."

It should also be recognized that despite Wright's claim that the GSC/IPC-message acceptance measures exhibit the same pattern of results, a close examination of these correlations shows that only the "acceptance (index)" measure shows the hypothesized reversal in importance which parallels the GSC/IPC-"original" counterargument pattern. (See Table 2). It is apparent that this index should be closely related to the number of original counterargument cognitive response measure, since these responses contribute to the calculation of this index (i.e., $\sum w_j SA_j - \sum w_j CA_j - \sum w_k SD_k$). Note also that this index includes an additional perceptual influence stemming from the thought rating task (i.e., the subjective weighted importance ratings) which

might also affect the subsequent responses on IPC and GSC (e.g., "I rated my original thoughts as very important and therefore I guess I am "not at all lacking in self confidence."). The consistent relationships between both of these dependent variables (and not the others) with the GSC and IPC measures strongly suggests that the thoughts judging tasks affected the subsequent responses on the GSC and IPC measures. In summary, the experimental procedure employed by Wright offers an alternative explanation for the consistent relationships he observed.

So far this critique has argued that the likelihood of a carry-over effect (between the thought judging, i.e., classification of "originality" and "importance" and trait measures) was quite high. One question still remains as to why this effect only occurred in those particular conditions. The next portion of this paper will address this issue.

If one accepts Wright's argument that the high involvement-audio message is representative of a strainful and overt social influence situation (i.e., the uncontrolled message delivered by another person only once, after which the subject expects to make an important decision), then it seems clear that subjects would be experiencing a task which creates strong arousal potential. In this social comparison processing environment it appears likely that subjects' ratings of the number of "original" counterarguments and GSC would necessarily be correlated. On the other hand, consistent with Wright's hypotheses, IPC should not strongly relate to the number of "original" CA as the information-processing task orientation is subsumed by the pervasive social factors.

Compared with the high involvement treatment, the low involvement conditions exemplifies a less social and more task-oriented situation. Message receivers therefore place less emphasis on cognitive resistance activities inherent in the high involvement decision mode. The lack of personal decision making permits the information processing task environment to become more salient. Hence, the subjects' self-reports of IPC and number of "original" counterarguments are related in the low involvement condition. General Social Confidence is not a strongly related factor in this processing environment since the strong task orientation and lack of the personal decision mode diffuse the strength of a social orientation.

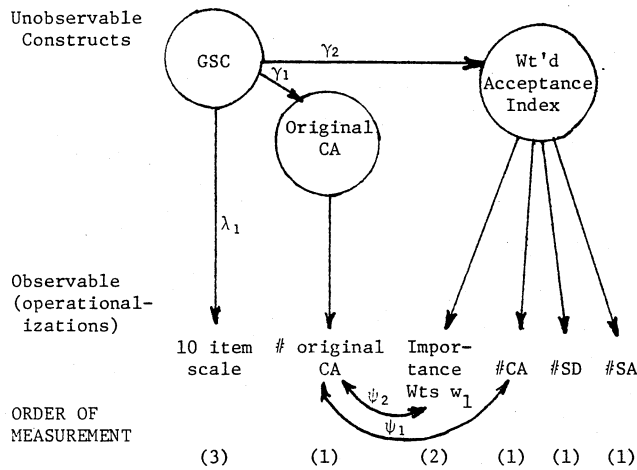

In summary, it appears that Wright's manipulations were effective in creating the desired processing environments. However, because the thought coding and importance weighting tasks immediately preceded the trait measurement, it appears that the conclusions regarding a "trait-affecting-cognitive response" causal relationship are unfounded.

The Issue of Interpretational Confounding. Figure 2 represents Wright's nomological network for the proposed General Social Confidence--"original" counterargument (i.e., GSC \rightarrow "original" CA) and General Social Confidence--Weighted message acceptance index (i.e., GSC \rightarrow Wt'd Acceptance Index) relationships. A similar nomological network exists and could be replicated for the IPC construct.

The model illustrates why one would necessarily expect significant correlations between the weighted message "acceptance (index)" and the GSC--"original" counterargument constructs. Because the number of "original" counterarguments has been utilized to operationalize both CA and the message acceptance index we have encountered a problem of interpretational confounding (Bagozzi 1980, p. 153). This general problem of ascertaining the meaning of theoretical variables i.e., interpretational confounding, "occurs as the assignment of empirical meaning to an unobservable variable which is other than the meaning assigned to it by an individual a priori to estimating unknown parameters" (Burt 1976, p. 4).

In Wright's model it appears that the γ_2 relationships is strongly influenced by the γ_1 relationship. Evidence for this premise can be obtained by examining the expected

FIGURE 2
Wright's Nomological Network

covariances ψ_1 and ψ_2 and by noting the temporal order of measurement.

The expected covariation between total number of counter-arguments (i.e., #CA) and the number of "original" counter-arguments (i.e., # original CA), (Noted as ψ_1), implies that the CA construct and weighted message acceptance construct are not conceptually distinct. The fact that other measures of message acceptance did not yield significant relationships with GSC/IPC provides additional credence for this premise.

The logic for the expected ψ_2 covariance is quite similar to that of ψ_1 . Additionally, because the # original CA and the importance weights observables represent self-reported measures subject to the earlier suggested biases of carry-over effects and arousal potential, these measures may share a considerable amount of covariance (i.e., ψ_2). A stronger test of theory would be to demonstrate a significant relationship between GSC and the weighted acceptance index while controlling for # original CA.

One additional rationale for the case of interpretational confounding involves the temporal order of measurement. As previously discussed, this ordering suggests that the causal relations γ_1 and γ_2 were actually reversed in the experimental setting. A final methodological issue concerns the validity of the GSC and IPC scales.

Factor Analysis of GSC/IPC. Measures of GSC and IPC were collected in two separate investigations by these researchers. In the first study (Swasy 1980) measures of GSC and IPC were collected for comparison with cognitive responses. Several aspects of this study closely resembled Wright's approach. These aspects included the use of an uncontrolled persuasive message (i.e., a videotaped sales presentation), similar sample of subjects (i.e., mothers, who were volunteer subjects and church group affiliates, $N = 249$), and who had a relatively high level of involvement with the topic (i.e., children's books). One important difference between this investigation and Wright's approach however, is that the GSC and IPC measures were collected one week prior to the experiment. Earlier arguments regarding possible carryover effects in Wright's design are eliminated with these pre-measures of GSC and IPC. No relationships between GSC and IPC with message acceptance or frequency of any cognitive responses were found. Subsequent orthogonal and oblique factor analyses of the GSC and IPC scales revealed that they were not unidimensional.

To reassess these findings a second investigation was conducted. A random sample ($N = 135$) of undergraduate college students completed a questionnaire which contained a number of attitude scales and the GSC and IPC measures. Factor analyses again revealed non-unidimensionality.

At a conceptual level, the oblique factor structure illustrates some interesting dimensions underlying the IPC and GSC scales. (See Tables 3 and 4). An assessment of these factors suggests that GSC contains both social and information processing subfactors. Although this is consistent with Wright's notion of the GSC construct, an examination of the IPC scales introduces some confusion. The IPC scale also appears to contain aspects of a "social" comparison (e.g., "I have more trouble concentrating than most people"). Although these factor analysis results are not a conclusive test of the scales' validity, they do suggest the need for a more systematic approach toward measuring individual differences.

One aspect of the scales' validity which should be addressed is the social desirability of the responses to these measures. In the survey of undergraduate college students, mentioned above, the Crowne/Marlowe Social Desirability Scale (1964) was also administered. For this sample, the GSC-SD correlation was .4449 ($p=.001$) and the IPC-SD correlation was .2094 ($p=.007$). These findings provide additional evidence of the weakness of the GSC and IPC measures and again suggest the possibility that a repertoire of subjective tasks such as judging the originality and importance of verbalized thoughts may also contain a high degree of social desirability bias which may be shared with the GSC/IPC scales.

Discussion

This paper has reviewed Wright's (1975) findings concerning the role of information processing traits influencing cognitive resistance to advertising. At a conceptual level, an examination of the methodological procedures suggests

that the experimental design affected the GSC and IPC measures. A thorough examination of the pattern of results in the study also suggests that the thought coding and judgment tasks created a response set which carried over to the GSC and IPC measures. Finally, examination of the GSC and IPC scales in two separate investigations showed that the scales may not be unidimensional.

Although "chronic" traits as conceptualized by Wright represent an important determinant of cognitive responses and message acceptance, work by Epstein (1979) suggests that multiple measures and multiple observations yield more meaningful and consistent relationships between trait and behavioral variables. This approach is necessarily more demanding of the research, however an interactionist perspective appears to necessitate such rigor.

In summary, for the study of GSC/IPC future research should:

- (1) reassess the dimensionality of the GSC/IPC scales via factor analysis;
- (2) address the GSC/IPC-social desirability issue for evidence of possible format changes in GSC/IPC scales (e.g., forced choice responses);
- (3) investigate the social desirability aspects of thought reporting and coding tasks; and
- (4) following an interactionist's position:
 - (a) measure traits over several occasions prior to the experimental situation, and
 - (b) observe cognitive responses and attitude change in several stressful information processing situations. These multiple measurements and observations over several similar situations will provide a stronger test of the cognitive mediators of persuasion.

DISCUSSION

Jagdish N. Sheth, University of Illinois

Introduction

There is very little in common among the three research papers included in this session except that they all relate to very different aspects of consumer information as opposed to consumer choice behavior. Therefore, I will first discuss each research paper separately and then make some observations about consumer information as an area of research and theory. In order to conserve space, I will not summarize the findings and conclusions of each paper. Instead, I will simply discuss its strengths and weaknesses.

Consumer Information Programs

The first paper by Deshpande and Krishnan on establishing public policy priorities for consumer information programs based on market research findings is a very worthwhile and useful contribution to the discipline for at least three reasons. First, the research study adds to our very limited substantive knowledge about the information needs of the elderly consumers. Second, the authors provide a very neat conceptualization of information deficiency as a function of perceived need for information and perceived difficulty in obtaining it. In fact, the development of Information Deficiency Index may be the single most contribution of this paper. Finally, it represents a good application of Thurstone scaling procedures which have been neglected in the past in consumer research.

The paper, however, suffers from the "analysis overkill" syndrome. First of all, do policy makers really need or worse yet care about the relative magnitudes of information deficiency across the nine buying experiences? Would they not be just as happy and content to know the ranking of nine buying experiences? I seriously doubt that policy makers can even utilize the Thurstone interval scale points for budget allocation purposes since it is arbitrary, lacking in an absolute anchor point, and definitely subject to change by addition of other buying experiences to the list.

Ironically, the authors do have a more meaningful and useful quantitative scale in their Information Deficiency Index. It is an absolute score ranging in value from one to three. Average or median scores of nine buying experiences with respect to the index do represent aggregate market scale points which are at least interval scaled and, therefore, quantitative measures. In short, I fail to see any need for applying the Thurstone Case V Model to the data.

Finally, there are so many other more meaningful ways to generate relative magnitudes of information deficiency out of this data bank. For example, calculating the proportion of consumers who answered yes to both perceived need and access difficulty will provide a ratio scale which will remain invariant to addition of other buying experiences. Alternatively, one can calculate the mean deficiency score and perform a normal deviate analysis to generate standard scores of information deficiency among the nine buying experiences. Of course, this distribution will be subject to sampling problems but with a large number of buying experiences, it will reach limits and stabilize as a normal distribution.

A more interesting and useful analysis of the data is to identify those elderly consumers who really need information. For example, it would be very interesting to profile the "yes-yes" group (score three) in terms of demographic and socioeconomic variables: do they come from certain ethnic

minorities or are they concentrated in some regions of the country? If our past research is any guide, it is very likely that there is a hardcore segment within the elderly consumers which is most information deficient across all nine buying experiences. The public policy makers and the society as a whole will be better off if consumer information programs are targeted toward those who really need them. Otherwise, we will keep on repeating our past program mistakes such as unit pricing, nutrition labeling, and truth-in-packaging. As I have recently stated, unfortunately one law of consumer behavior is that those consumers who need information, do not use it (Sheth 1979) and, therefore, public policy efforts should be targeted toward them in terms of understanding and motivating them to use information.

Information Content of Non-Information

The second research paper by David Finn is an interesting study on how inferential beliefs enable consumers to add and subtract from what is communicated by the experimenter or the marketer. This study reminds of the neglected concept of stimulus-as-coded (s-a-c) proposed by Howard-Sheth theory of buyer behavior (Howard and Sheth 1969). According to their theory, prior attitudes and beliefs control overt search, attention and perceptual bias mechanisms with which stimulus-as-presented is modified into stimulus-as-coded. Recently, I have also discussed how advertising impacts on the consumer including many incidental, unintended and negative effects based on the stimulus-as-coded concept (Sheth 1974). I am, therefore, not as surprised as David Finn that consumers use phantom information.

There are also several methodological and conceptual problems with this study. First of all, post-test-only control group design simply cannot measure change as asserted by the author. It only measures differences between two groups, which is not the same thing as pre-post change. Second, although the control and test groups are randomly divided and belong to the demographically homogeneous population, it does not ensure that the two groups are psychologically homogeneous in terms of general toothpaste beliefs. Since the post-test control group is used as a benchmark, it is most critical to validate that the test group also has a comparable belief profile. One way to do this is to obtain population parameters about toothpaste beliefs and compare them with the sample parameters (control group). Otherwise, one can easily obtain perhaps a very different set of results by using another control group.

Finally, a closer examination of the mean differences among beliefs reveals that the greatest differences occurred for most probable (seal of approval, about the same price) and least probable beliefs (made with new type fluoride). Furthermore, lack of confirmation reduced the probability of most probable beliefs (-2.391 and -1.153), whereas highly assertive message increased the probability of least probable belief (1.300). I find this as evidence of what one would expect from all the cognitive consistency theories including the cognitive dissonance, congruence and assimilation-contrast models.

My own view is that projective techniques, rumor-transfer, story-telling and word association types of research may

be more relevant if we want to know the information content of non-information.

Information Processing Traits

It is amusing to critique a critique when you are not the author who is critiqued! I am sure Peter Wright does not need me to respond to the criticisms levied by Munch and Swazy. And, I am not eager to defend this research tradition either, simply because it is statistically uninteresting and frustrating by being loaded with correlations which gain significance from large samples rather than any evidence of true relationships between traits and information processing.

I do agree with Munch and Swazy about these three methodological and conceptual problems in Wright's study. First, there is a very definite social desirability bias in scales designed to measure General Social Confidence (GSC) and Information Processing Confidence (IPC). This is easy to detect from the skewed distributions of subject responses. In fact, I will go one step further and assert that most correlations based on these scales are likely to be biased and inflated and, therefore, encourage the experimenter to eagerly commit the type one error (rejecting the null hypothesis when it is true).

Second, there is conceptually strong support for the multidimensionality of constructs as complex as GSC and IPC. If they are multidimensional, as Munch and Swazy claim from their own research findings, it is very difficult to make causal inferences based on univariate analysis of variance techniques. You need to utilize path analysis or structural equation modeling procedures for testing the hypothesis.

Third, Munch and Swazy correctly point out the problem of intercorrelation between GSC and IPC. One can even argue that General Social Confidence (GSC) cannot be achieved by or attributed to someone who does not have Information Processing Confidence (IPC). In our society, individuals who think slowly, cannot concentrate, are at a loss for words or not quick-witted, do not emerge as either self-confident or socially confident individuals. I am, therefore, quite surprised that Wright chose to treat them as separate and orthogonal factors in his research study.

The Wright study and its critique by Munch and Swazy once again points out the age old admonition: Measure your independent constructs such as GSC and IPC more specific to the criterion situation. We must develop statements for both GSC and IPC which are directly related to advertising or at least consumer information oriented to ensure that both sides of the equation are at the same level of correspondence or specificity. Both personality researchers (Cohen 1967), and attitude researchers (Fishbein and Ajzen 1975) have belabored this point for so many years. However, we seem to ignore their admonition.

Observations on Consumer Information Research

Consumer information as an area of scientific research and theory is at its infancy in consumer behavior. Howard and Sheth (1969) pointed out, quite some time ago, that we know at least something about the learning constructs (attitudes, intention, beliefs and motives), but we virtually know very little about the perceptual constructs (attention, ambiguity, perceptual bias, overt search). It is, therefore, premature to conduct deductive research, either by developing theories or by borrowing constructs from other disciplines in this area. Instead, we must do considerable amount of empirical inductive research. In short, we must learn how to crawl before we start walking or worse yet, running.

Accordingly, we must lean toward more exploratory and qual-

itative research tools and tactics such as focused group interviews, projective techniques, clinical methodologies, and nonstructured surveys rather than experimental designs, construct development and measurement or laboratory studies.

In my opinion, consumer behavior as a discipline has already begun the shift from learning constructs such as attitudes and beliefs to the perceptual constructs such as consumer information's content, storage, retrieval and processing aspects. Contrast this year's ACR Proceedings with the proceedings of 1976 or 1977, for example.

EVOKED SET FORMATION AND COMPOSITION:
AN EMPIRICAL INVESTIGATION UNDER A ROUTINIZED RESPONSE BEHAVIOR SITUATION

Jacques E. Brisoux, University of Quebec at Three-Rivers
Michel Laroche, Concordia University

Abstract

The purpose of this study is to test some hypotheses regarding evoked set formation under routinized response behavior for regular beer drinkers under a specific scenario. By using a decomposition approach of the perceptual product space, and individual configurations, it is found that the best decision model is the conjunctive one, and that all brands included in the evoked set are previously tried.

b. Evoked sets are formed by considering all brands in the awareness set at the same point in time, and in this case the most appropriate decision rules are the linear compensatory and lexicographic models. If a new brand enters the awareness set, the whole process is repeated. The results of Parkinson and Reilly are congruent with the second conceptualization, although the authors call for caution in interpreting their results due to a number of methodological factors: Low sample sizes, student respondents, halo effects, and measurement problems (1979 p. 229).

Introduction

Evoked Set

The proliferation of brands occurring in the consumer goods markets create information processing problems for the consumers. They must often devise means to simplify their purchase decisions. One of the results of this simplification process is the existence of what Howard has referred to as "evoked set," which include the brands the buyer considers when he contemplates purchasing a unit of the product class (Howard 1963, Howard and Sheth 1969). First empirically studied by Campbell (1969), the concept of evoked set has caused a growing interest from researchers in consumer behavior (Ostlund 1973, Jarvis and Wilcox 1973, Grønhaug 1973-1974, May and Homans 1976, Williams and Etzel 1976, Maddox et al. 1977, Belonax and Mittelstaedt 1977, Parkinson and Reilly 1979).

Inert and Inept Sets

Narayana and Markin (1975) have suggested a more complete conceptualization of the output of the consumer's simplification process: The individual may not be aware of all the brands available (total set) at time of purchase. This leads to the concepts of awareness set and unawareness set. Within the former any brand is categorized as either evoked, inept or inert. According to Narayana and Markin, a brand would belong to the evoked set if it were considered for purchase by the consumer and evaluated positively. It would be in the inept set if it were rejected from the consumer's purchase consideration and evaluated negatively. Finally, it would be in the inert set if it were neither accepted nor rejected by the consumer and evaluated neither positively nor negatively (p. 2). The measurement of the first two sets is done through direct questioning only on the buying consideration dimension, while the inert set is inferred by deduction of the first two from the awareness set (p. 3). As they noted later, the evaluations attached to the different sets are a precondition to the consumer choice behavior (Narayana and Markin 1976).

Evoked Set Formation and Composition

In his review of the papers by Belonax (1979), May (1979), and Parkinson and Reilly (1979), Myers (1979) raises a number of conceptual and methodological issues concerning the temporal aspects of evoked set formation and composition. He suggests two alternative conceptualizations of these processes:

a. "Evoked sets are formed over time by considering each new entry into the awareness set whenever it comes along. It would seem that a conjunctive or a disjunctive processing model would be much more appropriate for this type of evaluation." (p. 236).

Myers (1979) describes a phasing model by which consumers may establish their evoked set by using one cutoff model (i.e., conjunctive or disjunctive), followed by an evaluation for each brand within this set for purposes of choice by using a compensatory model. This conception is congruent with the findings by Best (1976), and Pras and Summers (1975), the propositions of Belonax and Mittelstaedt (1977) and Belonax (1979), as well as the paradigm developed by May (1979). This paradigm combines the information processing approach proposed by McGuire (1976) with the learning theoretical approach developed by Howard (1977). In particular, May suggests that Howard's three stages of concept learning, i.e., concept formation, attainment and utilization, correspond to the three levels of information processing complexity related to the exposure search and retrieval steps. The highest level of information processing complexity is required for the first learning stage (concept formation). The third learning stage (concept utilization) requires the least complexity.

Also, according to Howard (1977), at the concept formation stage, consumers identify their evoked set in terms of untried brands only. At the concept attainment stage they identify it in terms of mixed brands (i.e., untried and tried ones). At the concept utilization stage (Routinized Response Behavior), they identify it in terms of tried brands only.

The purpose of this research is to test what Myers called a phasing model, especially its first stage (i.e., a cutoff model is more appropriate), and to test some part of May's conceptualization of combining both learning and information processing hypotheses, including Howard's proposition of the evoked set composed of tried brands only in an RRB situation.

Methodology

In order to carry out this research and provide some control over possible sources of variation, a number of strategic decisions were made.

Purchase Scenario and Ideal Universe

The product class which was selected was beer to be purchased for regular and individual consumption by male beer drinkers in the evening before dinner within one major metropolitan area of Quebec (Canada), namely the Three-Rivers area. The scenario was selected because it is typical of beer consumption in that area. This decision is believed to be critical since the choice of a decision rule may be affected by situational factors (Hansen 1976), and

prior familiarity (Park 1976). The area selected is relatively homogeneous in terms of socio-demographic characteristics, and the ideal universe is defined as male drinkers residing within the region at the time of the study and consuming at least three 12 oz. bottles of beer a week. This operationalization of a regular drinker corresponds to the industry's definition. Finally, beer is a product at the maturity stage for most regular drinkers, and the purchase decision may be classified as Routinized Response Behavior (Howard 1977).

Sampling Method and Sample

The operational universe is restricted to the male regular beer drinkers, french speaking, 18 years old or more residing in the Three-Rivers, Shawinigan Metropolitan area. This area includes the cities of Three-Rivers, Cap-de-la-Madeleine, Shawinigan and Grand-Mère in the Province of Quebec and is located 90 miles east of Montreal. Its total population is about 150,000 people. In accordance with the rules of area sampling, residential streets were randomly selected from each city. On each street residences were then systematically selected. In each housing unit one regular male beer drinker was personally interviewed. In the case of several regular drinkers within a unit, only one was interviewed by randomly selecting by age. A total of 732 male subjects were contacted. Of these subjects 453 qualified as regular beer drinkers and 375 questionnaires were usable for the purpose of a much larger study than the one reported here and dealing with the content and size of evoked set (Brisoux 1980).

Data Collection

The data collection was done through personal structured interviews at the interviewee's residence. Each interviewer had an individual two hours training period and his work was checked regularly by a supervisor. Interviews were conducted mainly during the evening, and lasted about 80 minutes.

Questionnaire

The parts of the interview of concern here consisted of getting essentially three kinds of information:

- (1) Brand perceptions on selected scales: The selection of specific scales was made from the results of a factor analysis of the brand perceptions collected previously in a large scale (private) survey which used 37 scales. The decision to limit to 11 the number of scales was due to the fact that respondents had to rate 13 brands of beer available plus an ideal brand. Respondents were asked to rate all brands they were aware of one attribute at a time on a 9-point bipolar scale like the following one:

Light • Heavy

The other labels used were

Sweet/Bitter
 No/Much after taste
 Easy/Difficult to digest
 Does not create/Creates some discomfort (headache, stomach ache, etc.)
 Has less/more calories than the average beer
 Very/Little pronounced taste
 Very/Little tart taste
 Becoming less/more popular
 Would/Would not serve it to my friends
 Less/More salty taste than the average beer

Finally the wording of each scale was based on the most common semantic structure of regular beer drinkers

(Allaire 1972).

- (2) Brand classifications: During the interview, each respondent was given a set of thirteen cards, in random order, each with a different authentic beer label (aided recall procedure). The respondent was then asked to indicate the brands of which he was aware, and the others were discarded. Next, using the remaining cards, he was asked through a sequence of questions to classify each brand into one of three categories (Narayana and Markin 1975):
 - (a) The evoked set consisting of the brand which he would consider buying for his personal consumption in the evening before dinner, plus other acceptable brands to be bought for the same purpose;
 - (b) The inept set consisting of the brands the consumer would refuse to buy for the same consumption situation;
 - (c) The inert set consisting of the remaining brands, i.e., those which he would not consider nor reject.
- (3) Prior experience: The respondent was given a list of brands and asked to indicate which ones he had tried before.

Analysis

The purpose of the analysis was to develop a perceptual space for each segment within our sample and decompose this space according to some compensatory and non-compensatory decision models. The analysis proceeded in steps:

Step 1: By using the data on brand perceptions, determine if there are any segments of homogeneous perceptions.
